Abstract—FT-GReLoSSS (FTG) is a C++/MPI framework to ease the development of fault-tolerant parallel applications belonging to a SPMD family termed GReLoSSS. The originality of FTG is to rely on the MoLOToF programming model principles to facilitate the addition of an efficient checkpoint-based fault tolerance at the application level. Main features of MoLOToF encompass a structured application development based on fault-tolerant “skeletons” and lay emphasis on collaborations. The latter exist between the programmer, the framework and the underlying runtime middleware/environment. Together with the structured approach they contribute into achieving reduced checkpoint sizes, as well as reduced checkpoint and recovery overhead at runtime. This paper introduces the main principles of MoLOToF and the design of the FTG framework. To properly assess the framework’s ease of use for a programmer as well as fault tolerance efficiency, a series of benchmarks were conducted up to 128 nodes on a multicore PC cluster. These benchmarks involved an existing parallel financial application for gas storage valuation, originally developed in collaboration with EDF company, and a rewritten version which made use of the FTG framework and its features. Experiments results display low-overhead compared to existing system-level counterparts.

Keywords—distributed fault tolerance; application-level checkpointing; SPMD paradigm; framework; skeletons

I. Introduction

As a result of increased competition, many industries have strived for new, more accurate simulation models. Their design, assessment and exploitation often requires huge amounts of computational power which eventually led those industries to adopt high performance distributed systems (HPDS).

In many cases, computations may be broken into several independent parts which can straightforwardly exploit HPDS. However, not all computations fit efficiently the embarrassingly parallel computation model. Programmers with little parallel background face three major issues. Firstly, they need to learn how to make their applications run efficiently on HPDS. Secondly, as the probability of failure increases with the number of computational resources (or nodes) used, developed applications have to be robust and fault-tolerant. Finally, HPDS systems involve rapidly evolving hardware and software which compels the use of portable fault tolerance (FT) solutions. Efficiency of these solutions is not an option as industrial environments are subject to time constraints: for example, some long-running applications in financial institutions are run overnight, and their results are expected in the morning in order to decide on the daily strategy to follow. Hence, FT efficiency translates into little slowdown of applications during failure-free time intervals. In case of failure, it translates into little wasted work and short restart times.

Checkpointing is a widely spread FT technique which consists in periodically saving the application state to stable storage. Following a failure, application execution is interrupted and the most recent saved state is then used to resume execution. This paper presents FTG, a specialized framework derived from the MoLOToF programming model [1]. MoLOToF aims to facilitate the development of efficient parallel applications and their endowment with efficient application-level checkpointing.

After covering related works (Section II), we describe the MoLOToF programming model and the software architecture of the FTG programming framework (Sections III and IV). Ease of development is assessed through the use of FTG on an existing industrial application for gas storage valuation from EDF company (Section V). Finally, the efficiency of the approach is evaluated experimentally (Section VI) before concluding (Section VII).

II. Related Works

Existing FT research for message passing applications has focused a lot on transparency. By combining a sequential checkpointer (e.g.: BLCR [2], MTCP [3] . . . ) and some rollback recovery (RR) protocol, it was possible to endow existing MPI libraries such as OpenMPI [4] or MPICH [5] with transparent FT or to provide more general solutions such as DMTCP [6] for socket-based distributed applications. RR protocols ensure that individual checkpoints of MPI processes remain consistent despite interdependencies created by communications: they form a recovery line. Most available solutions implement a so called blocking RR protocol which “freezes” communications while a checkpoint is made.
introduction of programming model for fault tolerance named MoLOToF. The calculations among processes. It differs by relying on a specific approach, frameworks also facilitate writing parallel applications. As a framework, FTG shares similarities with PUL-RD and Cactus as far as the parallelization model is concerned. All three involve iterative calculations with two approaches, frameworks also facilitate writing parallel applications. As a framework, FTG shares similarities with PUL-RD and Cactus as far as the parallelization model is concerned. All three involve iterative calculations with two array datastructures, swapped at the end of each iteration.

On the other end, FT can be tackled manually. Though not clearly stated in the litterature, the manual approach to FT is not unusual. Admittedly, the approach is tedious even with the aid of third-party libraries (e.g.: TCS [9], SCR [10] checkpointing libraries). Nevertheless, resulting FT is very efficient and portable, and the user may improve it further based on his knowledge of the application. For production applications, the efficiency gained quickly outweighs the endeavour.

Finally, users can rely upon frameworks to achieve FT. PUL-RD [11] and Cactus [12] are examples where users are subject to some programming constraints in exchange of which they benefit among others from FT. Compared to the previous two approaches, frameworks also facilitate writing parallel applications. As a framework, FTG shares similarities with PUL-RD and Cactus as far as the parallelization model is concerned. All three involve iterative calculations with two array datastructures, swapped at the end of each iteration.

FTG supports applications with non-trivial distribution of calculations among processes. It differs by relying on a specific programming model for fault tolerance named MoLOToF. The introduction of fault-tolerant skeletons yields an explicit structuration of the application, which in turn provides a simple, yet efficient, way to endow applications with FT. Hence, users are led to “actively” interact with the framework. Our fault-tolerant skeletons are inspired by the skeleton programming approach, and are designed at lower level. Hence they should be named “sub-skeletons” (or “low-level skeletons”). But for simplicity, in the rest of this paper we call them “skeletons”.

III. MoLOToF PROGRAMMING MODEL FOR FT

MoLOToF (Model for Low-Overhead Tolerance of Faults) is a programming model geared towards easing the development of fault-tolerant parallel applications. MoLOToF relies (1) on a peculiar structuring of the application and (2) on establishing collaborations through inter-

A. Skeleton-based code structuring

Using fault-tolerant skeletons, the application is split into two broad types of code operations: heavy and light operations. Heavy operations correspond to time-consuming code. Such code is usually found within calculation and communication phases of a skeleton. Light operations designate every other piece of code which is really fast to reexecute, and hence not interesting to checkpoint. Such separation results in a straightforward save/restore (checkpointing) mechanism based on application reexecution. To illustrate the mechanics, let us assume an application made of a single skeleton as the one in fig. 1. As represented in fig. 2, the application comprises an initialization phase, a skeleton and a cleanup phase.

During normal application execution (cf. Fig. 3), checkpointing occurs whenever a checkpoint location and a checkpoint condition are met. In our example, a checkpoint occurs on the second iteration. Among saved data is the iterator’s value (i.e.: 2). Consistency of individual checkpoints is ensured by some adapted RR protocol. An application executes until it quits gracefully or until a failure occurs. In our example it fails somewhere during communications of the third iteration.

After the detection of a failure (cf. Fig. 4), the application is restarted from its most recent recovery line: here, the checkpoint taken at iteration 2. The application enters recovery mode (cf. “restarting:true” in fig. 4). Namely, each process restarts from the very beginning as in its initial run til it reaches the checkpoint location where the checkpoint it is supposed to restart from was achieved. During this course, only light operations are reexecuted therefore resulting in fast restarts. When reaching the appropriate checkpoint location, application context is restored. To complete recovery, checkpoint file contents are loaded back into the application, which can then normally resume its execution: the application falls back into normal execution mode (cf. “restarting:false” in fig. 4) and resumes with the third iteration.

is a framework named FT-SPMD [1] which targets a broad family of SPMD applications named GReLoSSS (cf. Section IV). FT-SPMD benefitted from several modifications in its architecture and API which resulted in a seriously improved version called FT-GReLoSSS (FTG for short) which is presented hereafter. Compared to [1] the framework architecture is presented more in-depth and it is validated using an industrial application (cf. Section IV).

IV. FTG PROGRAMMING FRAMEWORK

A. GReLoSSS computation model

The GReLoSSS (Globally Relaxed, Locally Strict Synchronization SPMD) parallel computation model encompasses SPMD applications consisting in a main loop where each iteration (or superstep) contains a calculation and a communication phase. Such applications follow globally a classic BSP scheme [15]. However, these applications differ from BSP in two ways:

1) to improve efficiency on big parallel architectures, algorithms do not have a global synchronization between supersteps: each process starts its next superstep as soon as it has issued, but not necessarily completed, all its communications. Hence, global synchronization is relaxed as in the PRO model [16].

2) yet, to improve checkpointing efficiency, each process completes all its communications before starting the next superstep. Dependencies due to communications between processes disappear and consistent checkpointing is facilitated. Hence, compared to PRO, GReLoSSS has a locally strict synchronization which prevents overlapping of calculations with communications.

B. Application class supported by GReLoSSS and examples

The applications of the class supported by FTG (FT-GReLoSSS) involve two array datastructures one of which contains data used in the current superstep. The role of the second one depends on the application. A domain decomposition application such as Jacobi relaxations [17] will use that datastructure to store new results at the current superstep. A data circulation application such as in some parallel matrix multiplication algorithms [1] will use it to receive data for the next superstep from neighbouring processes.

During communications, processes exchange data corresponding to initial data or to intermediary results. Communications between processes may be quite varied, yet, in most cases, they are sufficiently foreseeable to be specified by the programmer. For example, in a Jacobi relaxations application, it consists in exchanging borders (or shadow regions) between...
subdomains assigned to different processes. A subdomain designates the subset of the entire domain which was assigned to a process. Thus, a subdomain has the same datatype as array datastructures. At the end of communications, the two array datastructures are swapped.

Algorithms using two array datastructures (of 1 or more dimensions) such as the ones described may seem restrictive. But from our experience, they cover the needs of a fairly wide class of applications.

C. Software architecture and features

FTG is a C++ framework implementing programming principles described in MoLOToF. It is built on top of the MPI specification which makes it compatible with every MPI library. It provides a set of classes to ease the development of fault-tolerant GReLoSSS parallel applications.

Relations between main FTG classes are depicted in fig. 5. The ftg_Skel class represents a GReLoSSS skeleton and comprises:

- a calculation kernel (cf. ftg_Calc_Kern) which provides the calculation method and the skeleton’s main loop iterator. It is also possible to specify a condition for communications achievement.
- a routing plan (cf. ftg_Routing_plan) which is responsible for determining and scheduling communication exchanges between processes.
- a checkpoint (cf. ftg_Checkpoint) which sets the location in the skeleton where checkpoints will be taken.
- two array datastructures (cf. ftg_Domain) as introduced previously in the GReLoSSS computation model (cf. Sections IV-A and IV-B).

![FTG UML class diagram](image)

The source code excerpt of ftg_Skel class (cf. Fig. 6) shows how these abstractions are layed out within the execute method. The resulting structure closely follows the example skeleton in fig. 1. It differs in the existence of conditional communications (l. 50-51) and the presence of a swap method (l. 61) where the two datastructures exchange their data according to the GReLoSSS computation model.

Condition has to be verified globally: all processes enter communication phase or none. Notice the name prefixes: ftgu_ are user-provided (l. 29-30, 41, 44), ftg_ are framework provided (l. 16), and ftgf_ are framework-provided based on user-provided methods (l. 38).

Concerning FT, the GReLoSSS skeleton defines a check-point right after the swap operation. By default, it contains data internal to the skeleton such as the two datastructures and skeleton iterators. ftg_Skel exposes to the programmer an interface allowing him to control data to include in the check-point. Furthermore, data which can be included in checkpoint files has to be either a primitive C++ type or derived from the framework’s ftg_Serializable class (cf. Fig. 5), in which case the programmer has to provide a pair of save and load methods. This approach was used within FTG to make ftg_Domain and ftg_Domain_desc classes serializable. The latter is a helper class which describes the extent of a domain (or subdomain) along each dimension.

Upon instantiation of the skeleton, the user has to inform the routing plan whether application communication consists in borders exchanges or in circulating data. Aside from this, he may choose among different communication schemes. Currently, the routing plan integrates two schemes based on the MPI_Isend-MPI_Irecv pair of MPI primitives. The first scheme performs all communications in parallel, while the second tries to “pace” them so that there is only a limited amount of ongoing concurrent communications at a time [18]. Concerning data movement, the routing plan groups sparse data into contiguous large messages and also minimizes copies from/to communication buffers by detecting ranges of contiguous elements. This last feature proved useful in applications where data to transfer is contiguous as it avoids using intermediate buffers.

The calculation kernel is merely made of pure virtual methods which the programmer has to define.

The array datastructure provides the programmer with an interface to N-dimensional arrays enclosed in ftg_Domain. When interfacing his own array datastructure (by inheriting from ftg_Domain), the programmer provides information regarding (1) the way the domain is split among processes as well as (2) the way to access an element given its coordinates \((x_1, x_2, \ldots, x_n)\). Moreover, the programmer provides information regarding the storage order. In 2D, C storage order consists in storing the array line-wise, while a Fortran storage order consists in storing the array column-wise. Storage order generalizes in higher dimensions and can lead to more different storages depending on the order of storing each dimension.

Since the interface proposed by ftg_Domain targets N-dimensional domains, it manipulates a vector of coordinates which can be inconvenient to the programmer in small dimensions. It can also be less efficient. Therefore, FTG proposes specific interfaces for dimensions 2 and 3 (resp. ftg_Domain2D and ftg_Domain3D in fig. 5).

Finally, after splitting a domain among processes (cf. Fig. 7), any given element can be located either relative to the first element of the entire domain or relative to the first element of

Fig. 7: Global versus local array access.

the subdomain it belongs to (resp. Global ref and Local ref in fig. 7). The first are called global coordinates while
the second are called local coordinates.

FTG allows the programmer to use either of them without any further involvement. Access through local coordinates is
preferable since it is faster, but it is not always the most convenient. Using global coordinates incurs a slight overhead
due to an additional offset computation.

From a design standpoint, the use of dynamic polymorphism
(through classic inheritance) is sufficient. However, since array
access methods are often used, the resulting overhead is
tremendous. That is why FTG relies also on static polymorphism,
and more specifically on the Curiously Recurring Template Pattern (CRTP) [19].

In the following section, we describe the Swing application
and the steps to interface it efficiently with FTG.

V. Swing FINANCIAL APPLICATION MIGRATION

Due to house heating, demand in gas is higher in winter
than in summer. Gas is mainly provided by pipes that cannot
deliver more than a specific amount of gas per day and it
results in far higher gas prices in winter. In order to provide
energy to their customers, gas market actors have to own some
storages that can help them smooth peak demand. In order to
assess a project’s rentability, gas companies can use a financial
real option approach that can be implemented in a software.

A. Swing application goal and implementation

The Swing application is used at EDF company to valuate
a gas storage facing the energy market. It aims at giving
the average cash flow generated by the asset depending on some
prices scenario. It also gives the management and hedging
strategies [20]. These calculated strategies are used in a second
application simulating the way the storage is used. This second
application gives some cash flow distributions obtained by the
storage management. While the time needed for the second
application is short, the swing valuation can be very costly
depending on the price models used to generate scenarios. The
price models used at EDF for this software are a gaussian one-
factor model (g), a normal inverse gaussian model (nig), and a
two-factor gaussian model (g2d) [21]. The resolution method
for the Swing application is the dynamic programming method
that has been written in C++ and uses MPI for parallelization
following the methodology in [18]. It also makes extensive
use of the Blitz library for its convenient array manipulation
facilities [22], and is about 18380 logical lines of code.

From an algorithmic standpoint, the Swing application fits
perfectly the GReLoSSS computation model. While being a
domain decomposition application, it is more complex than
classic Jacobi relaxations. Indeed, over supersteps:

- calculations involve a subdomain of the entire calculation
domain; that subdomain may change;
- shadow regions between processes have no fixed extent
and may change as well.

To interface the existing application with FTG, we follow
some typical development steps which are described hereafter
and summarized in fig. 8.

B. Development workflow

As part of the typical development steps, we have to inherit
from ftg_Calc_Kern to define a calculation kernel:

```cpp
template <class T_numtype, int N_rank, class T_iter>
class Swing:
public ftg_Calc_Kern <T_numtype, N_rank, T_iter, Swing_Domain>
{ }
```

```cpp
template
<
class T_numtype, int N_rank, class T_iter>
```
Finally, the application’s main function consisted in instantiating a calculation kernel and using it to initialize and execute the GReLoSSS skeleton. The corresponding source code has to be enclosed between the initialization and finalization statements of the framework provided by the ftg_Cpr (Checkpoint recovery) singleton class (cf. Fig. 8). The last step consists in choosing relevant checkpoint data. In particular, we unregister from the checkpoint the Domain which is useless at the end of the iteration, and register some application specific data which is not restored upon recovery (by mere reexecution), and hence has to be saved.

C. Ease of development assessment

The definition of the calculation method within our Swing calculation kernel involves the reuse of calculation functions in Gas_storage_price, and access to data in Gas_storage_asset (cf. Fig. 8). Both classes stem from the original Swing application. Similarly, partition methods in our Swing_Domain class require access to data and code reuse from Gas_storage_asset.

The calculation and partition methods are usually the most time-consuming to write. Especially the partition methods, which are prone to error due to indexes. Since compatible partition functions already exist in the original parallel Swing application, it is a matter of adapting them to use ftg_Domain_desc type to describe subdomains. The same applies for the calculation method, but some pieces of code have to be rewritten to use the attributes provided by ftg_Domain instead of those provided by Blitz Arrays. In the process, the interface of Swing_Domain was enriched to allow efficient and convenient access to ranges of data.

Another challenge we encountered concerned efficiency. In particular, partition methods have to be really fast as they are often called by the framework either to access elements through global coordinates or to build the routing plan.

In the end, the full fault-tolerant Swing application with FTG is about 353 logical lines of code less than the original application. Provided we are careful, the resulting application displays a clean and simple design as shown in fig. 8. Moreover, the application is fault-tolerant and the programmer has less lines of code to write. As shown in the next section, performance is as good as without FTG, sometimes slightly better.

VI. PERFORMANCE EXPERIMENTS

The evaluation of FTG consists in a comparison with the popular OpenMPI (OMPI) library which implements a blocking checkpoint protocol in combination with BLCR. OMPI applications benefit from a system-level checkpoint/restart solution. Experiments led, assess FTG and OMPI performances without and with FT enabled. When FT is enabled, checkpoints are taken, and we consider application runtimes in the failure-free case and recovery times otherwise. We also consider checkpoint size reduction and their impact on runtime overhead.

In these experiments, we consider temporary crash failures of nodes which can be dealt with by having both FTG and
OMPI store checkpoints locally to each node (i.e.: /tmp). Also, this setting avoids disrupting measurements due to additional communications resulting from significant data transfer across the network.

A. Testbed description

Experiments were led on the Intercell cluster hosted at SUPELEC. Intercell features 256 nodes running on 64-bit Fedora Core 8 and interconnected through a CISCO 6509 Gigabit Ethernet switch. Each node has an Intel Xeon-3075 dual-core processor (i.e.: a total of 512 cores) and 4 GB of RAM. However, experiments were run with one process per node. Benchmarks applications use OpenMPI 1.5.3 and were compiled with g++ 4.1.2 compiler and --O3 optimization flag.

B. Runtime overheads comparison in absence of checkpoints

Fig. 9 shows that FTG exhibits negligible to no overhead for the g2d price model, and scales well up to 256 nodes where it performs better than the application not using FTG. Similar results were observed for the g and nig price models.

C. Checkpoint size

Checkpoint size is dominated by the size of the two array datastructures used for parallelization. Since at the end of a superstep, the input data is useless, it can be omitted from the checkpoint. This optimization results in checkpoint sizes per node twice as light compared to system-level checkpoints (cf. Fig. 10). The same can be observed for the g and nig models. These models require less memory and result in checkpoints size ranging between 20 MB and several kilobytes with FTG compared to 40 MB at 7 MB for OMPI BLCR. In what follows, we focus on the g2d model: its’ long runtimes make it a good candidate for FT.

D. Fault tolerance performance without failures

For this experiment, we have run both versions of our application with the g2d model and different number of checkpoints: the lengthier the benchmark the more checkpoints were achieved in order to minimize the wasted amount of time in case of failure. In the present experiments we set the maximum allowed wasted amount of time to 4 minutes. Fig. 11 reports the runtimes on 128, 64 and 32 nodes. The plots compare OMPI with BLCR and FTG. In the latter’s case we measured runtimes without and with checkpoint size optimization in an attempt to quantify the impact of checkpoint size reduction. The difference remains marginal (0 – 3%) and is the highest with the biggest checkpoint sizes as the ones involved on 32 nodes. The difference is expected to grow further with bulkier checkpoint files. The remaining overhead observed with OMPI-BLCR ranges between 6% and 40%. Overhead incurred by FTG is always lower and does not exceed 8% in all cases. OMPI-BLCR’s overhead is mainly attributed to its blocking checkpoint protocol [4], which, unlike FTG’s protocol, involves communications and “freezes” the application execution in order to checkpoint.

E. Recovery overhead

Recovery from a checkpoint comprises (1) a negotiation phase where processes decide from which recovery line to recover, followed by a (2) context recovery phase, and finally (3) a recovery from checkpoint file phase (i.e.: time to load data). Measured negotiation phase time is negligible (< 10ms). Context recovery phase is small as well. Overall recovery time from a checkpoint is rather small as it does not exceed 1s for the g2d model on 128, 64 and 32 nodes. Thus, fast restarts combined with the low-overhead checkpointing pointed out earlier make FTG suited for applications with time constraints.

VII. CONCLUSION AND PERSPECTIVES

Endowing parallel applications with efficient checkpoint-based FT at the application level can be a tedious task which adds up to the existing difficulties of parallelization. Our approach based on the MoLOToF programming model introduces fault-tolerant skeletons and results in a tractable way for users to endow efficient fault tolerance into their applications. Moreover, combined with a specialized framework, MoLOToF eases parallel programming, and encourages a synergy between the user, the framework and the runtime environment to improve FT efficiency. MoLOToF is applied to the GReLoSSS family of applications which we characterized in this paper. The application of the resulting FTG framework to an industrial application of EDF company showed that initial development with FTG involved simple steps and points out some elements to watch in order to minimize runtime overhead. Finally, experiments show the effectiveness of the overall approach and especially the efficiency of FT. For the same number of checkpoints achieved, FTG yields smaller checkpoint sizes than OMPI-BLCR and incurs at most 8%
Future works are planned along the aforementioned lines. The approach appears viable for hybrid GP-GPU applications. FTG was implemented with. Moreover, due to its inherent portability, the fault-tolerant ecosystems, still have to be integrated and experimented with. But some of them, such as the integration with fault-tolerant SPMD applications [1].

Many principles of MoLOToF were used in the design of FTG. But some of them, such as the integration with fault-tolerant ecosystems, still have to be integrated and experimented with. Moreover, due to its inherent portability, the approach appears viable for hybrid GP-GPU applications. FTG might further be extended to support other parallelization models such as asynchronous distributed iterative algorithms. Future works are planned along the aforementioned lines.
