## Abstract

For electricity distribution companies, being able to accurately detect the position of buried power cables using nondestructive methods is a crucial issue. The most important issue is the localization of the junction part linking the cables to each other where most maintenance operations are carried out. In this work we have conducted a feasibility study to confirm the relevance of high frequency Ground Penetrating Radar (GPR) to detect these buried junctions in their environment despite the clutter. The cables are buried in an inhomogeneous Earth medium at about one meter deep. Consequently, we have optimized a folded bowtie antenna to fit the frequency band [0.5 GHz - 3 GHz]. Then a rigorous model of the cable is considered in the numerical study using the optimized antenna in a bi-static configuration. A full wave electromagnetic simulation software (CST MWS) has been used to study the detectability of the junction within dry and wet homogeneous sands then a classical Kirchhoff migration technique has been used to process the data and localize the junction. Finally, our analysis has been validated by measurements at a test site (real environment) to show the efficiency of the proposed analysis. The measured data are also post-processed using a digital filtering technique for clutter reduction and visibility enhancement of the buried cable.

## 1. Introduction

Ground penetrating radar (GPR) is a well-known non-invasive system used for identification and localization of buried cables, pipes and targets [1]. It is based on radars using electromagnetic waves to illuminate the ground using specific antennas. Echoes are collected and analyzed in order to image the underground. The wave propagates through it and when it reaches an electromagnetic contrast, the scattered field collected by the receiving antenna contains dielectric and geometric information about this contrast. Thanks to such information content of the signal, GPR is used in civil engineering [2], transport applications and road diagnostics [3–5], and soil moisture mapping [6–10]. GPR techniques are also used on masonry building to locate metal reinforcement [11, 12] or for mapping of archeological sites [13]. Using GPR, rebar position and depth can be evaluated with good accuracy [14–18] however, their diameters are difficult to estimate [17].

In the following, we will focus our work on the detection and localization of the junction that connects two or more buried power cables using a GPR system and the collected B-scan along the latter. The junction is represented

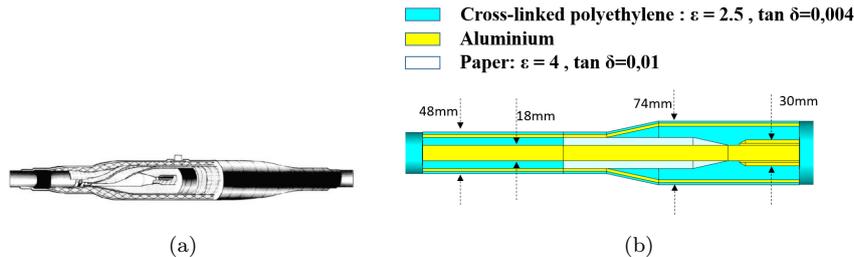

Figure 1: (a) A photograph of the junction of underground electrical cables, (b) The junction detailed description for the electromagnetic modeling purpose, the junction length is 40 cm

13 as the part of the power cable with a diameter outgrowth of 50 % compared with the one of the cable. Such a  
 14 diameter variation modifies the scattered field enough to distinguish the junction from the cable. The power cables  
 15 are usually buried at 1 m depth in sandy environments ( $\epsilon_r \sim 4$ ) and an example of real buried junction is presented  
 16 in Figure 1 where geometric details are provided. This is one of the smallest junction used by Electricité De France  
 17 Company (EDF). This work, aims at showing that a wide band GPR system covering the frequency band [0.5 GHz  
 18 - 3 GHz] can allow us to reach the needed resolution (3 cm) to distinguish the contrast between the scattered fields  
 19 due to the cable and the junction.

20 Thanks to the help of a full wave software (CST MWS) and its Finite Integration Technique a folded bowtie an-  
 21 tenna operating at the frequency band [0.5 GHz, 3 GHz] has been optimized and various scenarios have been studied  
 22 either in terms of embedding Earth medium (dry/wet sand) or in terms of polarization (parallel/perpendicular).  
 23 The geometric and electric description of the power cable embedded in a homogeneous dry or wet sandbox re-  
 24 spectively are considered in the numerical model and the optimized antenna is used as transmitting and receiving  
 25 structures. In fact, the authors of [19–26] have underlined the importance of the incident field modeling on the  
 26 GPR imaging results. The corresponding received signal ( $S_{21}$ ) in a bi-static configuration along the buried scanned  
 27 cable is then collected and treated using various filters in order to remove the clutter. Finally, the measurements  
 28 are realized inside a controlled area of “EDF - R&D” company with the laboratory of electrical material at Moret  
 29 sur Loing site where multiple cables are buried and where the presented GPR study has been validated. The paper  
 30 is organized as follows: section 2 is dedicated to describing the designed antenna. Section 3 proposes the full-wave  
 31 simulation results for the junction detectability. Section 4 focuses on the on-site measurement results conducted at  
 32 Moret sur Loing. Finally, a conclusion is drawn to outline the interest of the conducted study for utilities detection  
 33 and localization in section 5.

## 34 2. The GPR antenna structure

35 Ultra wideband antennas are widely used for GPR applications [27, 28]. These antennas can be TEM horn  
 36 [29], biconical antenna [30], the bowtie, the lumped element loaded antennas [31]. Here an optimized fractal folded  
 37 bow-tie antenna for on-ground GPR has been chosen. This antenna is used in the vicinity of the soil (proximal  
 38 antenna). Such an antenna belongs to the dipole antennas family, which is efficient and easy to design since the  
 39 input port impedance depends on the flare angle of the bowtie. We have optimized the antenna with its symmetric  
 40 excitation (BALUN) for the frequency band [0.5 GHz – 3 GHz]. The geometrical description of the antenna is given  
 41 in Figure 2 where the BALUN is also described. The antenna has been optimized in free space using the transient

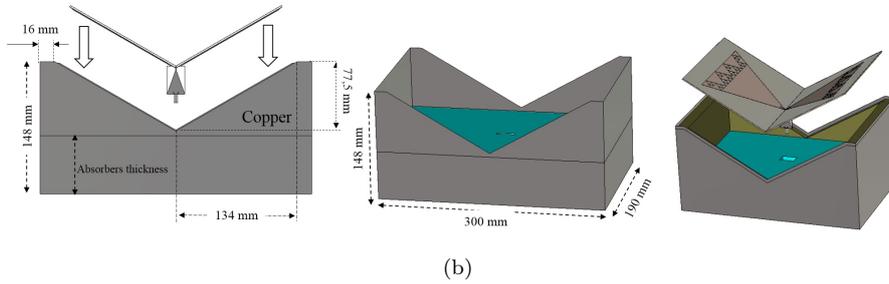

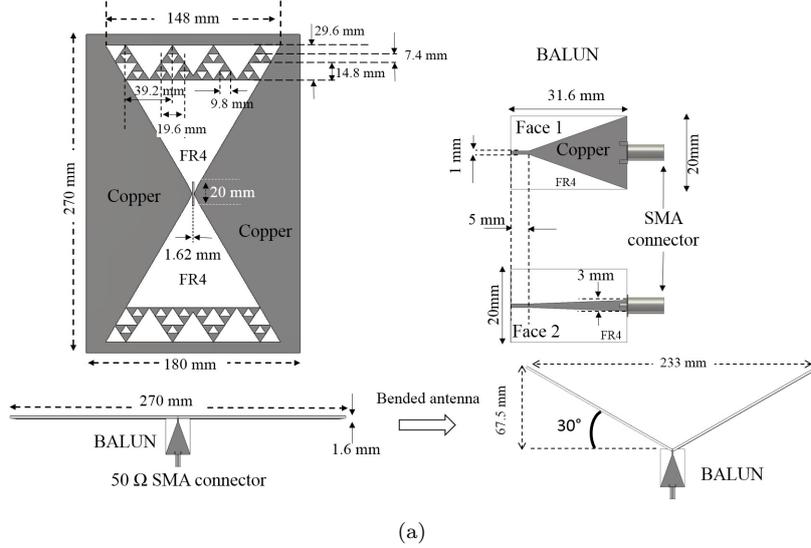

Figure 2: (a) V-Folded Bowtie Antenna (VFBA) description, (b) the cavity backed VFBA description.

42 solver provided by CST MWS and the measured reflection coefficient ( $S_{11}$ ) of the realized antenna is presented in  
 43 Figure 3. In order to prevent the back-radiation of the antenna we need to transform it to unidirectional one. We  
 44 can use a cavity as specified in many papers among which [32, 33] where a large cavity in comparison with the  
 45 bowtie antenna size has been used. However, such a solution is not adapted to the GPR application since the size  
 46 of the cavity has to be comparable with the size of the antenna as presented in [34]. Nevertheless, the use of the  
 47 cavity is inevitable because of the electromagnetic energy radiated from the back of the bow-tie antenna. Without  
 48 a shielding around the antenna, the interferences with the external parasitic electromagnetic perturbations reduce  
 49 significantly the signal to noise ratio of the measured data. In fact, the metallic cavity brings the protection to the  
 50 GPR antennas and without a specific precaution, the coupling between the antenna and the shielding cavity will  
 51 inevitably deteriorate the antenna matching.

52 In this paper we propose, besides using the cavity filled with absorbers, to bend the fractal bowtie antenna (as  
 53 shown in Figure 2) to enhance the directivity of the antenna in the frequency band of interest [0.5 GHz – 3 GHz].  
 54 The idea of bending the antenna is inspired from TEM antennas as depicted in [35].

55 The 30° bended antenna is labeled V-Folded Bowtie Antenna (VFBA). As shown in Figure 3, the VFBA  $S_{11}$   
 56 is presented and compared with the  $S_{11}$  of the VFBA with the shielding cavity filled with absorbers. The cavity  
 57 backed VFBA presents  $S_{11} < -10$  dB for the frequency band [0.75 GHz – 3 GHz] and the cavity filled with absorbers  
 58 did not disturb significantly the VFBA reflection coefficient ( $S_{11}$ ) over the frequency band [0.75 GHz – 3 GHz].

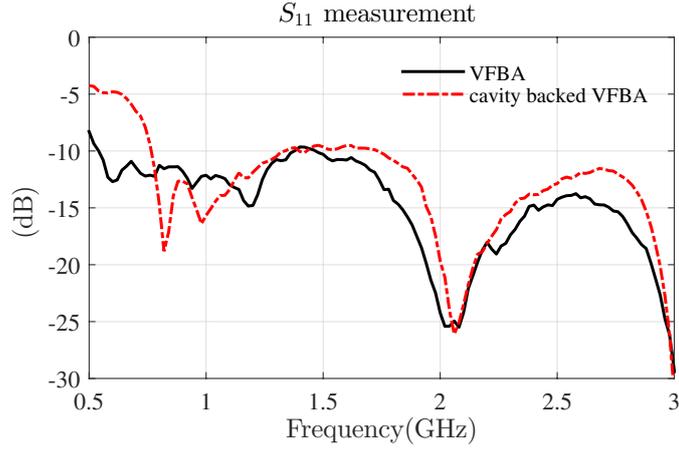

Figure 3: The measured reflection coefficients ( $S_{11}$ ) of the cavity backed VFBA and the VFBA.

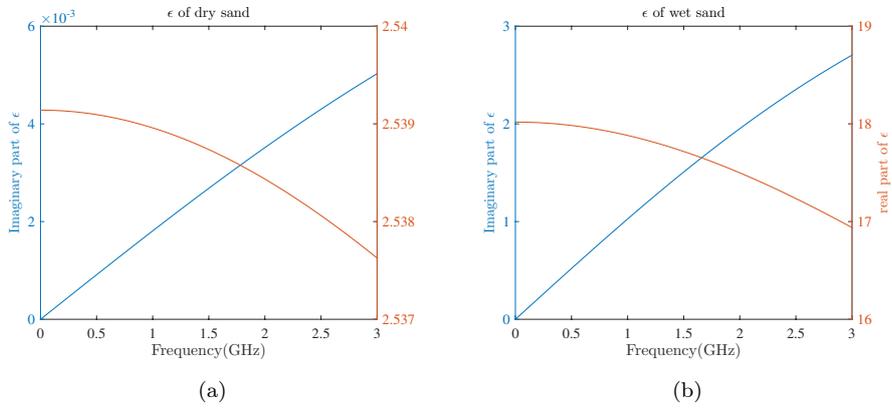

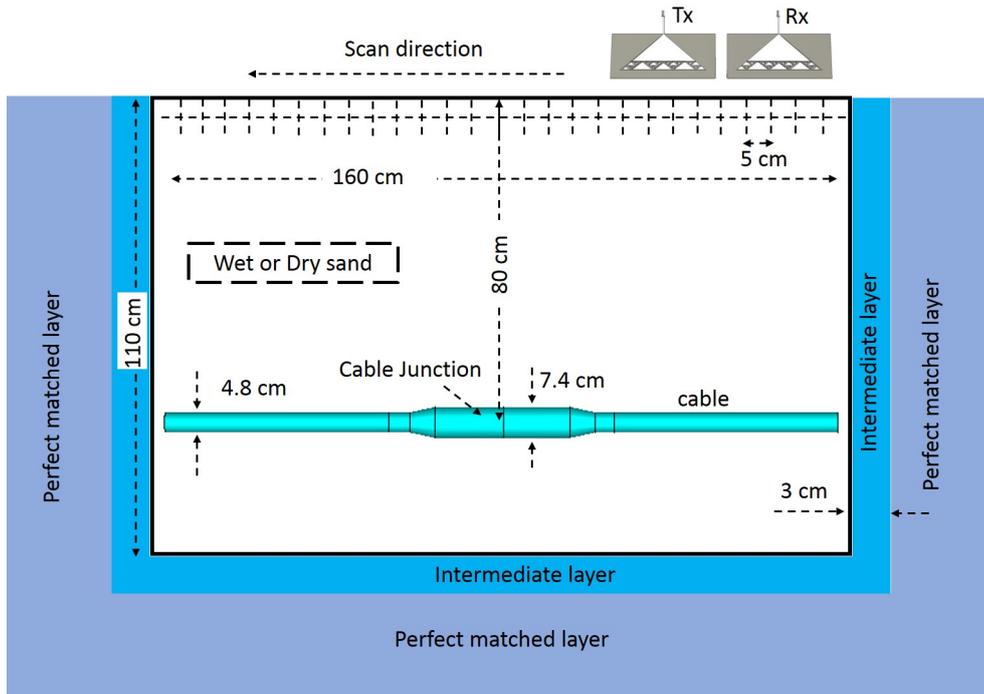

Figure 4: Permittivity of the sand used for the electromagnetic simulation, (a) dry sand, (b) wet sand.

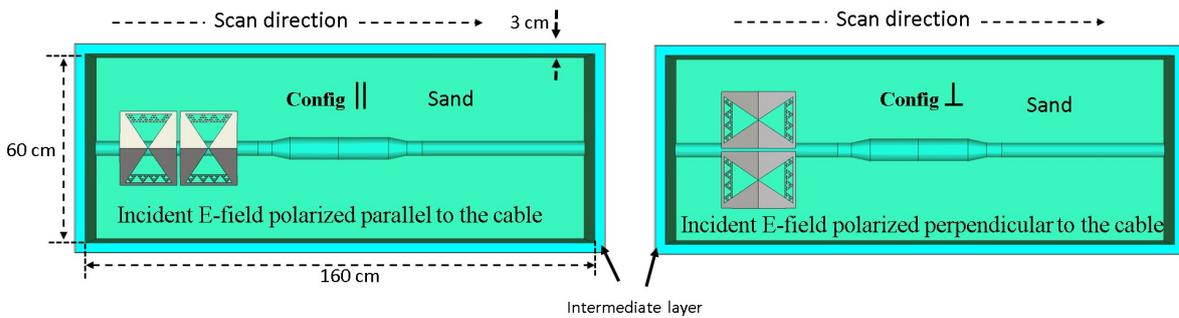

### 59 3. The electromagnetic modelling of the GPR scene

60 From now, the optimized VFBA will be used as transmitter and receiver to illuminate the scene and collect  
61 the scattered field due to a buried cable in dry or wet sands. The permittivity of wet sand is defined for 20 %  
62 humidity. The permittivity values used for our simulation are predefined in the CST MWS library and their real  
63 and imaginary part are given in Figure 4 whereas the GPR scene modeled in our study is described in Figure 5.  
64 Keeping the simulation time reasonably short (about 4 hours per antennas position) the cavity filled with absorbers  
65 for the antennas as shown in Figure 5 has not been considered. For the simulation of the GPR scene, we have used  
66 the transient solver of CST MWS with hexahedral meshing based on the spatial criterion  $dx = dy = dz = \lambda/12$   
67 where  $\lambda$  is calculated for the frequency 1.5 GHz. The total number of used mesh cells is 29 million for two VFBA  
68 placed in front of a sand volume of 1100 mm depth, 660 mm width and 1670 mm length.

69 The simulation is running on PC with 32 GByte RAM, over Intel Xeon CPU E5-1650 V3 3.5GHz. The excitation  
70 pulse is sent to the antenna via the coaxial connector of the BALUN and the simulation is stopped after 50 ns. For  
71 each position along the cable, this simulation takes 3h45min. In order to work with reduced size sandbox volume  
72 perfect matched layers (PML) have been used to prevent the echoes produced by the borders of the sand volume.  
73 For the case of dry sand scene, PML are placed around the sand volume to simulate an infinite sandy environment.  
74 For the case of a wet sand, the PML predefined in the CST software cannot deal with a dispersive environment and

(a)

(b)

Figure 5: (a) The simulation configuration with the buried cable, the sandy environment and the transmitting and receiving antennas, (b) description of the up-view of the simulation configuration associated with the polarization of the transmitting and receiving antennas

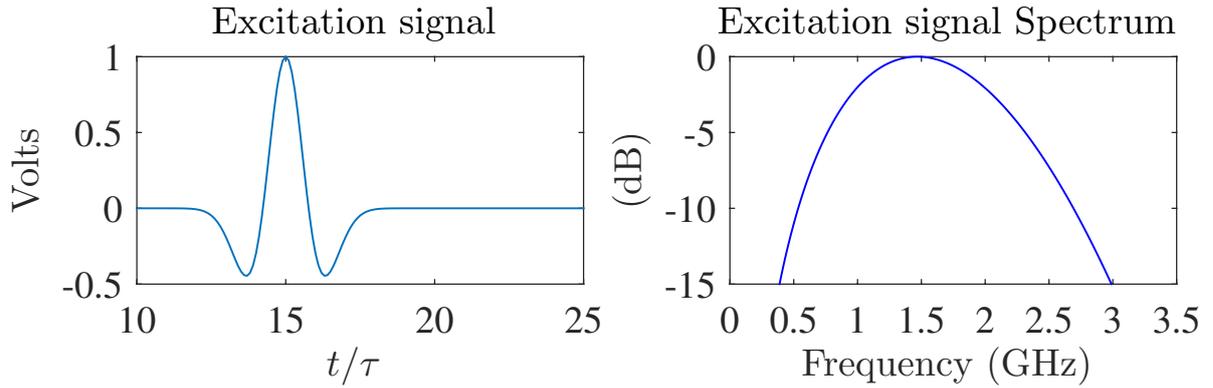

Figure 6: The used excitation signal and its frequency spectrum.

75 this is why an intermediate layer (IL) with a permittivity equal to the frequency-averaged value of the amplitude of  
76 the wet sand permittivity has been added. Adding the PML over the IL greatly helps in echoes attenuation. The  
77 PML play their role correctly since these have been defined for the IL containing non-dispersive material (Figure  
78 5). We have optimized the thickness of the IL using CST MWS in order to reduce the echoes produced by the sand  
79 volume limitations. The IL thickness optimization is not the main subject of the present study and will not be  
80 detailed in the following however in our case a value of 3 cm has allowed a sufficient reduction (cancellation is not  
81 reached) of the echoes produced by the sandbox borders. Another solution would have been to use a larger sandy  
82 volume and filter out the echoes but with an important increase of the CPU time (more than 12 hours calculation  
83 per antenna position for the double of the sand volume) with respect to the proposed solution.

84 The efficiency of the proposed solution for the echoes cancellation due to the sandbox boundaries is demonstrated  
85 by comparing the results of background modeling (the field without the buried cable) in three configurations. In  
86 configuration C-1 a wet sand volume placed in free space without perfect matched layers nor intermediate layers is  
87 considered, then configuration C-2 is defined as a wet sand with PML around the sand volume then configuration  
88 C-3, where a wet sand volume with the PML and IL as presented in Figure 5 is used. The electromagnetic  
89 simulations are carried out in the time domain and the transmitting antenna is excited using the second derivative  
90 of the Gaussian signal. The excitation signal is expressed as

$$e(t) = - \left[ 4\alpha^2 \left( \frac{t-t_0}{\tau} \right)^2 - 2\alpha \right] \exp \left[ -\alpha \left( \frac{t-t_0}{\tau} \right)^2 \right] \quad (1)$$

91 and its spectrum normalized at  $f_0 = 1.5$  GHz are presented in Figure 6 for  $\tau = 2 \times 10^{-10}$  s ,  $\alpha = 0.85/\tau^2$  and  
92  $t_0 = 15\tau$  which covers the antenna frequency band [0.5 GHz - 3 GHz].

93 For each antennas measurement position (A-scan), the receiving antenna collects the field scattered by the sand  
94 volume and the transmission coefficient  $S_{21}$  is exploited to construct the radargram presented in Figure 7a. The  
95 center of the sandbox is considered as the origin of the axis and the scanning is carried from  $[-0.5$  m,  $0.5$  m] with  
96 a displacement step of 5 cm.

97 As shown in Figure 7b, the combination of the PML and the IL (C-3) reduces significantly the echoes resulting  
98 from the limitation of the sand volume whereas in configurations C-1 and C-2 those echoes are still visible (mainly  
99 the echoes related to the bottom of the sand box around a depth of 1.2 m). For the three configurations, the cross-  
100 talk between the transmitting and receiving antennas is seen in Figure 7b where the A-scan corresponding to the

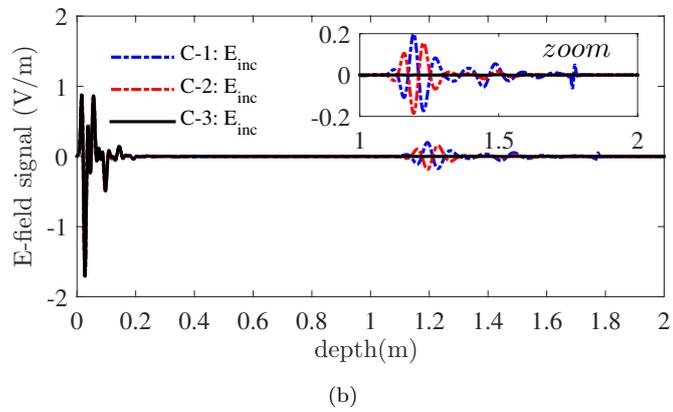

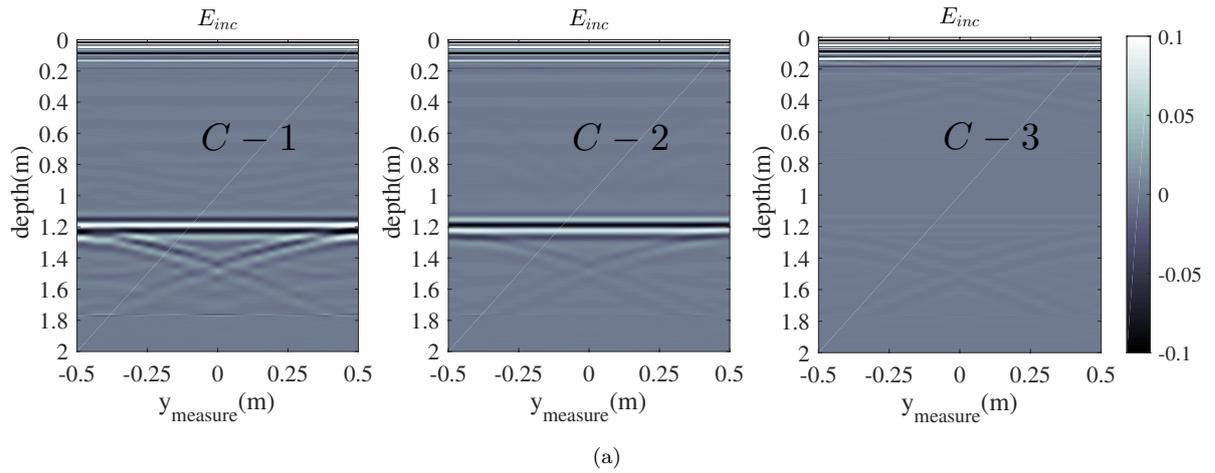

Figure 7: (a) The background modeling ( $E_{inc}$ ) for C-1, C-2, C-3 configurations (b) the A-scan of the central position  $y_{meas} = 0$  for C-1, C-2 and C-3 configurations.

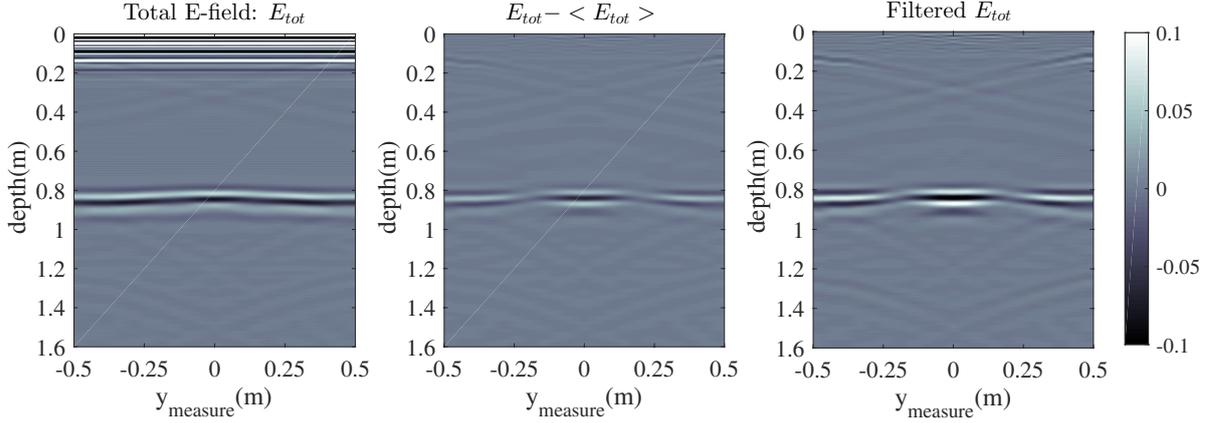

Figure 8: B-scan radargrams for  $E_{tot}$ ,  $E_{tot} - \langle E_{tot} \rangle$ , filtered  $E_{tot}$ , for parallel configuration with wet sand.

101 central position  $y_{meas} = 0$  m for C-1, C-2 and C-3 are compared, as seen in the zooming part the C-3 configuration  
 102 is efficient for the echoes attenuation. In the following, only the combination of the PML and IL will be considered.

103 Now a numerical study of the influence of the transmitting and receiving antennas polarization on the buried  
 104 cable detection is performed. In Figure 5b an upper-view of the antennas disposition above the sandbox is depicted.  
 105 In the first situation, the transmitting and receiving antennas are placed in order to align the polarization of the  
 106 incident field with the buried cable and consequently the impinging E-field polarization is parallel to the scan  
 107 direction along the cable (parallel configuration). In the second situation, the antennas are positioned so that the  
 108 incident E-field is polarized perpendicularly to the scan direction (perpendicular configuration).

109 Using CST MWS to model the scene presented in Figure 5 for a wet sand leads to the B-scan radargrams  
 110 presented in Figure 8 for the so-called parallel configuration. The total field ( $E_{tot}$ ) represents the measured field  
 111 over the sandbox in the presence of the buried cable. From the  $E_{tot}$  B-scan radargram, two clear echoes zones are  
 112 identified, the first one is due to the antennas cross-talk combined with the air-soil interface whereas the second one  
 113 is linked to the buried cable position. In order to get access to the scattered field, background removal techniques  
 114 are needed to isolate the signature of the buried cable. Among them, two have been used in the following. The first  
 115 one is one of the procedures described in [1] for clutter reduction by the GPR community, where the radargrams  
 116 resulting from  $E_{tot} - \langle E_{tot} \rangle$  where  $\langle E_{tot} \rangle$  means averaged value of the B-scan radargram of  $E_{tot}$  is used. The  
 117 second one is the digital filtering technique proposed in [36], which is based on the design of a digital filter adapted  
 118 to the B-scan. The high-pass filter to design aims at eliminating the clutter component in the spectral domain.  
 119 The filtered radargrams are presented in Figure 8. These two clutter reduction techniques have shown comparable  
 120 radargrams.

121 Four situations corresponding to dry and wet sand for parallel and perpendicular polarizations are studied and  
 122 the corresponding radargrams are presented either for  $E_{tot} - \langle E_{tot} \rangle$  and for filtered  $E_{tot}$  in Figure 9. In all of them  
 123 three areas can be identified in the signature of the buried cable. The first and the last areas corresponding to the  
 124 scanning positions  $0.25 \text{ m} < y_{meas} < 0.5 \text{ m}$  and  $-0.5 \text{ m} < y_{meas} < -0.25 \text{ m}$  characterize the echoes due to the cable.  
 125 The in-between second area shows the echoes due to the central part of the cable (junction) located at  $|y_{meas}| \leq 0.2 \text{ m}$   
 126 . The sloping parts of the cable junction (Figure 5) produce the echoes situated between  $(0.2 \text{ m} < y_{meas} < 0.25 \text{ m}$   
 127 and  $-0.25 \text{ m} < y_{meas} < -0.2 \text{ m})$ . The magnitude of the echoes gives qualitative information about the position of  
 128 the junction. In Figure 9 the cable junction is located at  $|y_{meas}| \leq 0.2 \text{ m}$  corresponding to the maximum magnitude

129 of  $E_{\text{tot}} - \langle E_{\text{tot}} \rangle$  and of the filtered  $E_{\text{tot}}$ .

130 As it is seen in Figure 9, the amplitude of the echoes resulting from dry sand are higher than for wet sand due  
131 to the higher propagation losses of the latter. As expected, the parallel antenna polarization produces higher level  
132 echoes compared with the perpendicular one. Based on these four studied situations, a common conclusion arises;  
133 the outgrowth of the cable diameter (junction position) is characterized by stronger echoes which are localized at  
134  $|y_{\text{meas}}| \leq 0.2$  m placed at 80 cm depth. When the antenna polarization is parallel to the cable, the impinging E-field  
135 is better coupled to the buried target, which increases the scattered echoes amplitude. On the contrary, in the  
136 perpendicular polarization, the coupling between the impinging E-field and the buried cable is lower, leading to a  
137 lower signature of the cable and its junction. As a conclusion and as expected in wet sand media, the radargram  
138 resolution is better and the parallel polarization is more efficient for the junction localization due to the strongest  
139 echoes amplitude.

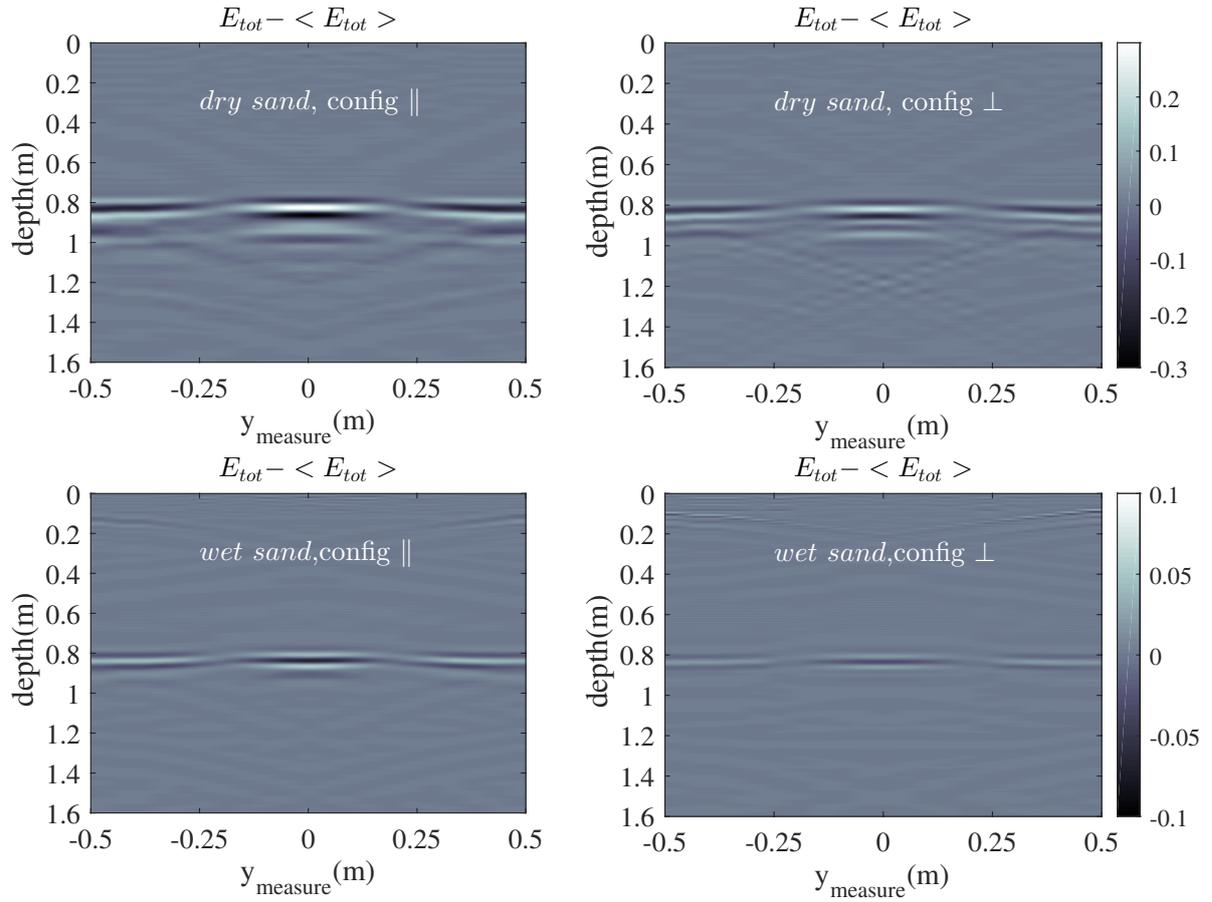

140 In order to have a better understanding of the behavior of the B-scan radargram at the intermediate area between  
141 the junction and the cable around  $y_{\text{meas}} = \pm 0.25$  m the A-scan signals of  $E_{\text{tot}}$  at the positions  $y_{\text{meas}} = 0$  m (junction),  
142  $y_{\text{meas}} = 0.25$  m (transition part) and  $y_{\text{meas}} = 0.4$  m (cable) are compared in Figure 10. Comparing the E-field for  
143 the two polarizations at the junction central position ( $y_{\text{meas}} = 0$  m) shows that the signal of parallel polarization  
144 results in a stronger signature. The outgrowth of the cable diameter at the junction position ( $y_{\text{meas}} = 0$  m) justifies  
145 the differences between the E-field signals at the positions  $y_{\text{meas}} = 0$  m and  $y_{\text{meas}} = 0.4$  m. In Figure 10, the A-scan  
146 signals show that the signal amplitude is proportional to the size of the scattering part of the cable. The position  
147  $y_{\text{meas}} = 0$  m corresponds to the largest diameter (74 mm),  $y_{\text{meas}} = 0.4$  m corresponds to the smallest diameter  
148 (48 mm) and the position  $y_{\text{meas}} = 0.25$  m is the intermediate region between the junction and the cable where the  
149 diameter is between 48 mm and 74 mm.

150 Finally, for imaging purpose a Kirchhoff migration technique [37–42] has been applied to the data of  $E_{\text{tot}} - \langle E_{\text{tot}} \rangle$   
151 and filtered  $E_{\text{tot}}$  and the results are shown in Figure 11. The buried cable and its junction are clearly identified  
152 either for dry sand or wet one and either for parallel polarization or for perpendicular one.

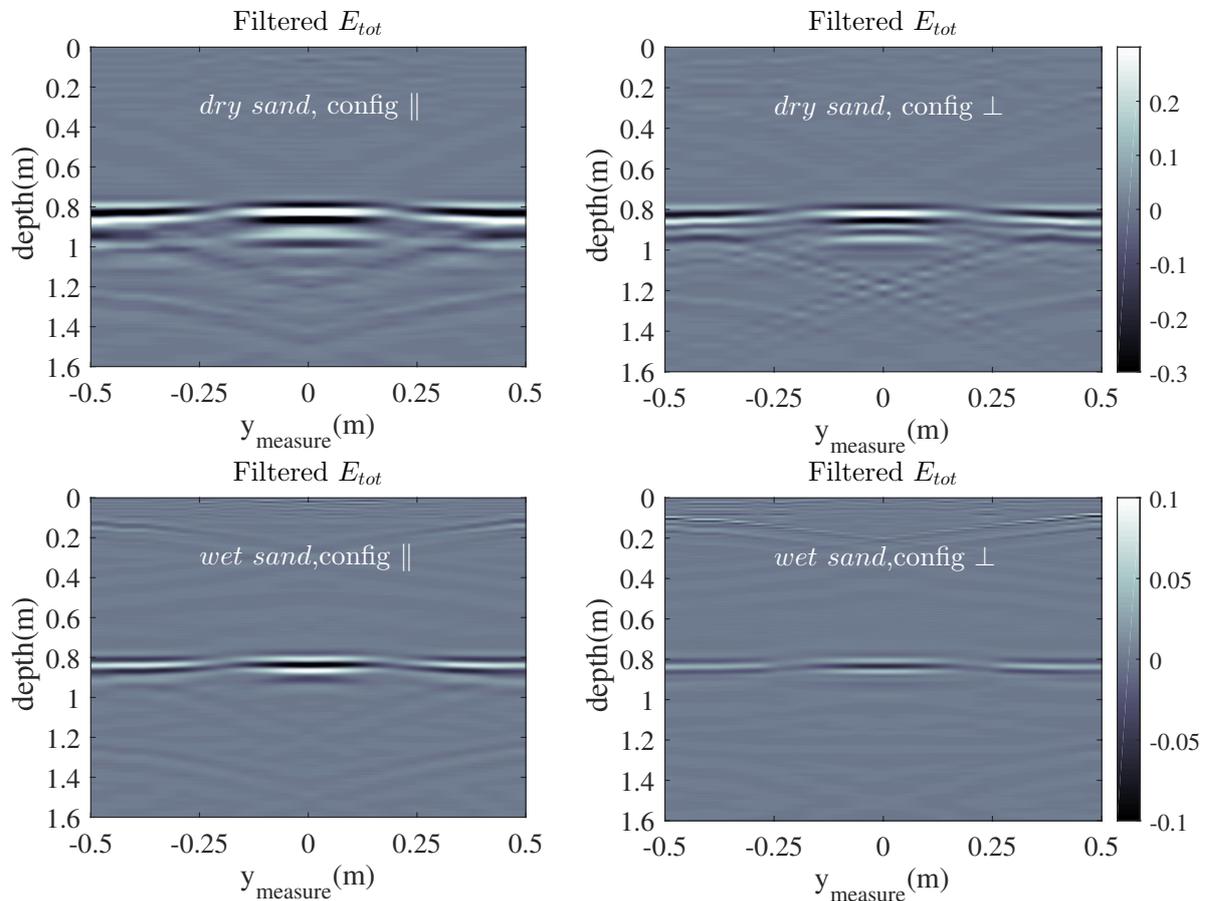

153 As a conclusion the simulation analysis of the GPR scene composed of a cable buried in a sandbox respecting  
154 different polarizations and for two commonly existing environments: dry sand and wet sand with 20% humidity is  
155 proposed. The actual fractal V-folded bowtie antennas (VFBA) are used in a bistatic configuration for transmitting  
156 and receiving the electromagnetic field in the frequency band [0.5 GHz – 3 GHz]. Up to here the electromagnetic  
157 (EM) modeling taking into account the coupling between the antennas and the sandbox was the main interest.  
158 The EM modeling has proven that the cable junction is detectable using a GPR technique in the frequency band  
159 [0.5 GHz - 3 GHz]. The results presented for  $E_{\text{tot}}$  are not trivial for the localization of the junction, however, using  
160  $E_{\text{tot}} - \langle E_{\text{tot}} \rangle$  and filtered  $E_{\text{tot}}$  the junction can be localized. The filtering technique is simply implemented for  
161 efficient clutter reduction as presented. In addition, the Kirchhoff migration technique has shown good results for  
162 the localization of the junction based on a unique B-scan along the buried cable. In the next part, the results with  
163 experimental on-site measurements will be carried out in a real (even if controlled) environment.

#### 164 4. On-site measurement results

165 We have carried out a measurement campaign inside a controlled area in “Electricité De France - R&D” company  
166 with the laboratory of electrical material at Moret sur Loing site (EDF lab Les Renardières). The photography

(a)  $E_{tot} - \langle E_{tot} \rangle$

(b) Filtered  $E_{tot}$

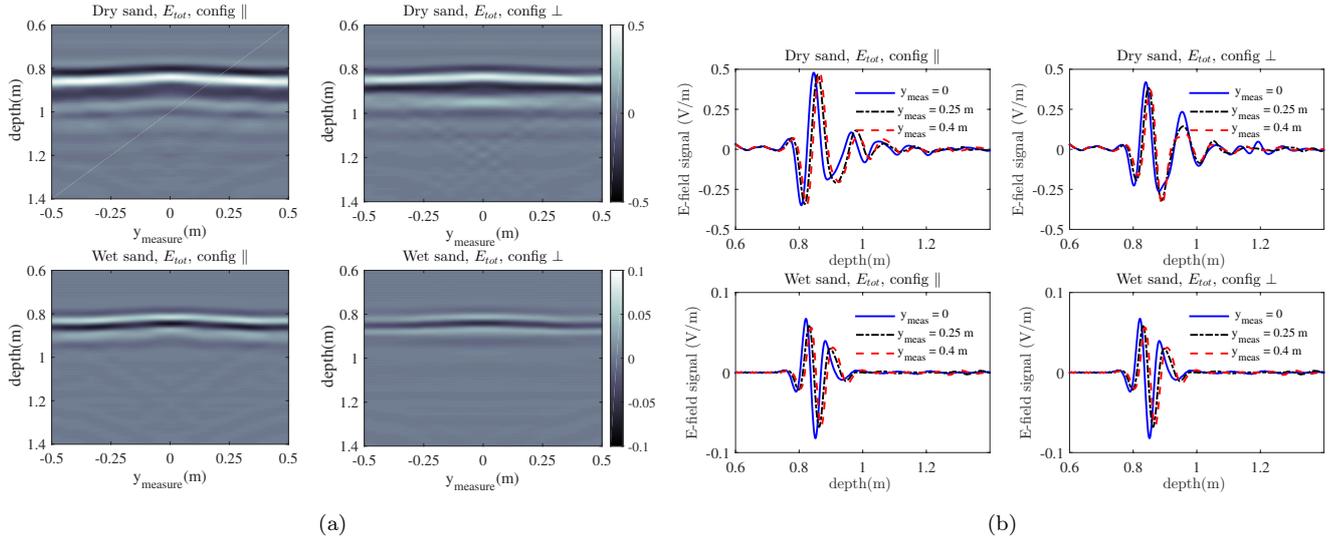

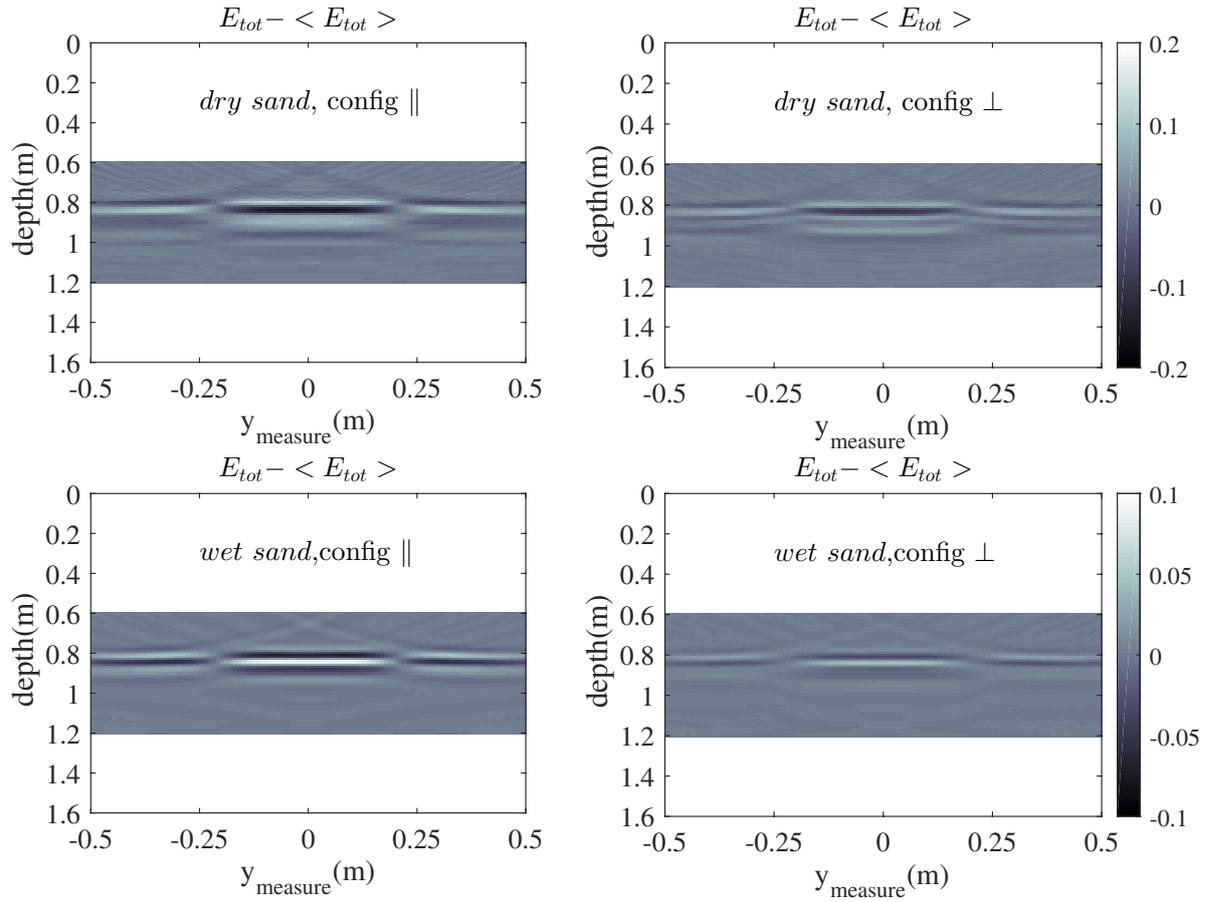

Figure 10: (a) Bscan radargram of the total field corresponding to the four studied situations. (b) Comparison of A-scan at  $y_{\text{meas}} = 0, 0.25, 0.4$  m.

167 of this site is depicted in Figure 12 and shows the measurement area and cables before being buried. The cables  
 168 are placed at around 1 m depth from the soil surface and the covers seen in the photography are removed before  
 169 burying the entire scene. We scanned over 4 m along a cable as shown in Figure 12, where the junction is localized  
 170 with the wooden stick (preserved after burying the cables) seen at the right of the photography.

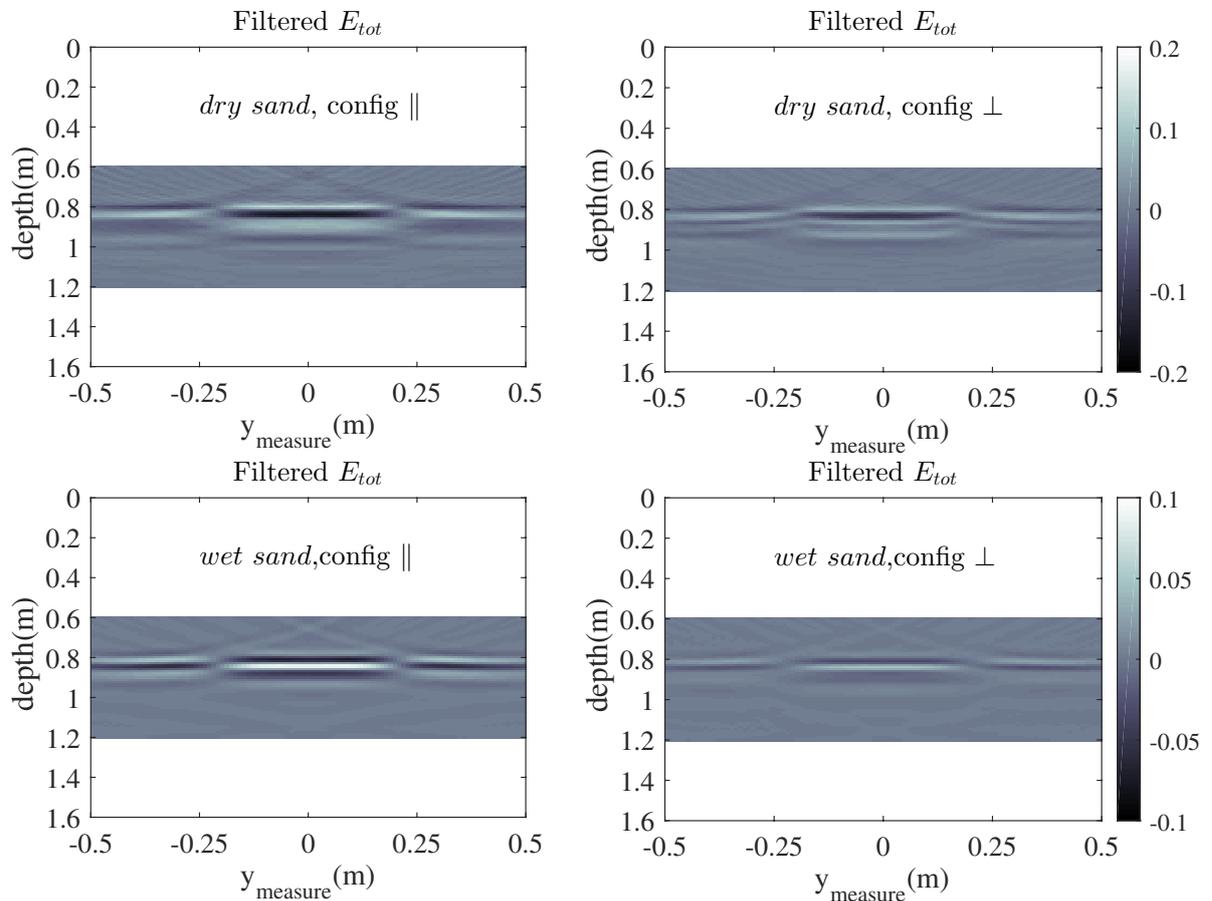

171 As seen in Figure 12, the buried cables are not identical to the simulated one; they are gathered by pair and  
 172 have a larger diameter (total diameter of about 90 mm) and the junction we are investigating is also larger since  
 173 it contains the junctions of two cables. The diameter of the buried junction is around 200 mm. The Frequency-  
 174 Stepped Continuous Wave (FSCW) GPR technique has been used to measure the scattered field using the cavity  
 175 backed V-folded fractal bowtie antennas and the vector network analyzer Agilent ENA E5071 in the frequency  
 176 band [0.1 GHz - 3.1 GHz] over 1201 frequency points (Figure 13). Then the frequency domain data are transformed  
 177 to extract the B-scan radargram according to the pulse previously depicted in Figure 6. For each measurement  
 178 position along the cable the controlling computer acquires the transmission parameter  $S_{21}$ . The measurement data  
 179 are collected along the scanning line presented in Figure 12 and the network analyzer has been calibrated before  
 180 starting the scan. The antennas are moved manually step by step along 4 m with a displacement step of 5 cm.  
 181 Unlike the simulation study the surface of the soil is not flat and the soil is not homogeneous.

182 In order to evaluate the wave velocity in the ground, we have collected a sample of the soil and we measured  
 183 the permittivity in the frequency band of interest using a coaxial probe in the laboratory. The results are shown  
 184 in Figure 14. The measured real part of the permittivity of the soil is about 2.69 and the imaginary part is about  
 185 0.07. Using the same permittivity measurement technique, we have measured the permittivity of the air as a  
 186 reference. Indeed, the average of the measured real part of the air permittivity is about 1.04 and the imaginary  
 187 part is about  $-0.006$ . These measurement results are used in the B-scan radargram representation to achieve the  
 188 time to distance transformation for the cable and junction localization. The measurement has been conducted in  
 189 July with a dry soil.

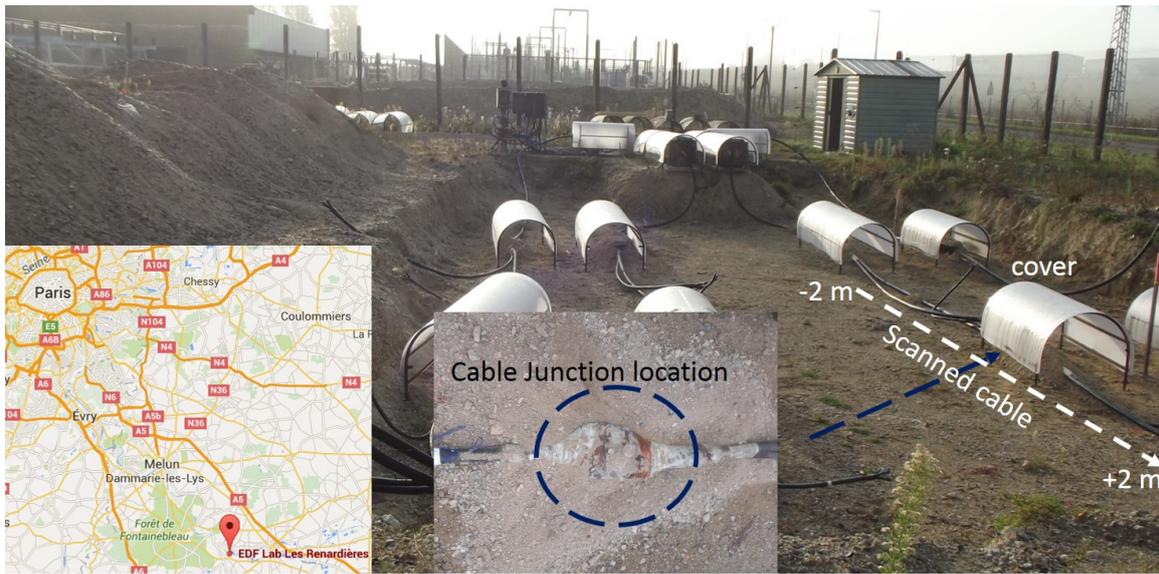

190 The B-scan is obtained for the parallel and perpendicular polarizations. The radargrams are presented in  
 191 Figure 15. In comparison with the simulation results, the clutter in the radargrams for  $E_{\text{tot}}$  is higher mainly

(a)  $E_{tot} - \langle E_{tot} \rangle$

(b) Filtered  $E_{tot}$

Measurement location

Figure 12: The measurement area at EDF-lab.

Figure 13: (left) Vector Network Analyzer and controlling computer, (right) transmitting and receiving antennas cavity backed V-folded bowtie antennas.

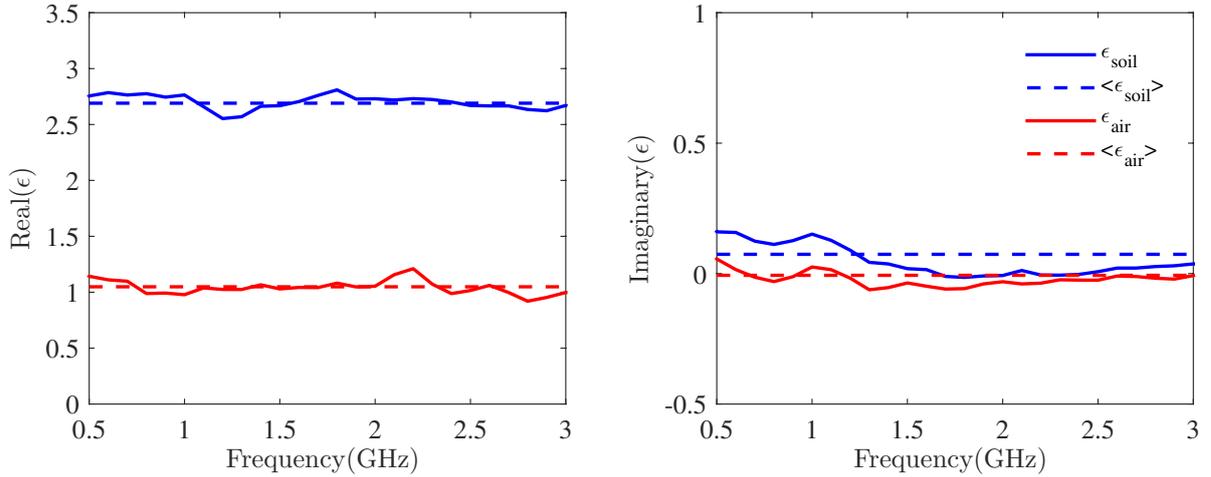

Figure 14: Measured epsilon of a sand sample collected at the measurement site, (left) real part, (right) imaginary part.

192 caused by the soil heterogeneities. In addition, the antennas response is differently coupled with the non-flat soil.  
 193 Using the cavity-backed antennas we prevent the external environment coupling, however we distort the shortness  
 194 of the antenna transient response. Based on the radargram of  $E_{\text{tot}}$ , the cable silhouette is clearly visible between  
 195 1 m and 1.4 m depth and the junction corresponds to the brightest zone at 1 m depth at the measurement position  
 196 0.5 m. This is applicable for both parallel and perpendicular polarizations.

197 We have focused our effort on the clutter reduction in the depth range  $0.8 \text{ m} < \text{depth} < 1.6 \text{ m}$ . After time  
 198 gating the measured signal, we have used two techniques for clutter reduction. First the averaging technique to  
 199 cancel a part of the clutter as presented in Figure 15,  $E_{\text{tot}} - \langle E_{\text{tot}} \rangle$  applied for  $0.8 \text{ m} < \text{depth} < 1.6 \text{ m}$  considerably  
 200 reduced the clutter and the cable is easily identified. In a second time, we have used the digital filtering technique  
 201 proposed in [36] with the same conclusion. Both techniques help at enhancing the detectability of the buried cable  
 202 and consequently the junction is localized at 1 m depth at the measurement position  $y_{\text{meas}} = 0.5 \text{ m}$  as expected.  
 203 The parallel polarization is more efficient than the perpendicular one which confirms the simulation results.

204 In Figure 16, we present the imaging results of the Kirchhoff migration technique resulting from the measurement  
 205 data. As it is seen, in the parallel configuration the cable and its junction are easily identified using  $E_{\text{tot}} - \langle E_{\text{tot}} \rangle$   
 206 and filtered  $E_{\text{tot}}$ . However, in the case of cluttered data, the cable is hardly detectable after the Kirchhoff migration  
 207 for the perpendicular configuration.

## 208 5. Conclusion

209 In this paper we have shown that the high frequency GPR technique is an efficient non-destructive technique able  
 210 to accurately detect the location of the buried power cables. Using a unique B-scan measurement along the cable,  
 211 the junction is clearly detected against the cluttered environment. As a priori information we know the position  
 212 of the cable. We have considered a complex GPR scene for our electromagnetic modeling study comprising the  
 213 actual antennas. Comparison between experimental data (anechoic chamber) and synthetic data either computed  
 214 using CST-MWS or using a laboratory-made software based on Discontinuous Galerkin Time-Domain method are  
 215 presented in [43, 44] and has not been reproduced here.

216 First, we have optimized the fractal V-folded bowtie antenna for the frequency band [0.5 GHz - 3 GHz]. Then,  
 217 we have presented the scattered field of a buried cable using a rigorous model of the cable provided by Electricity De

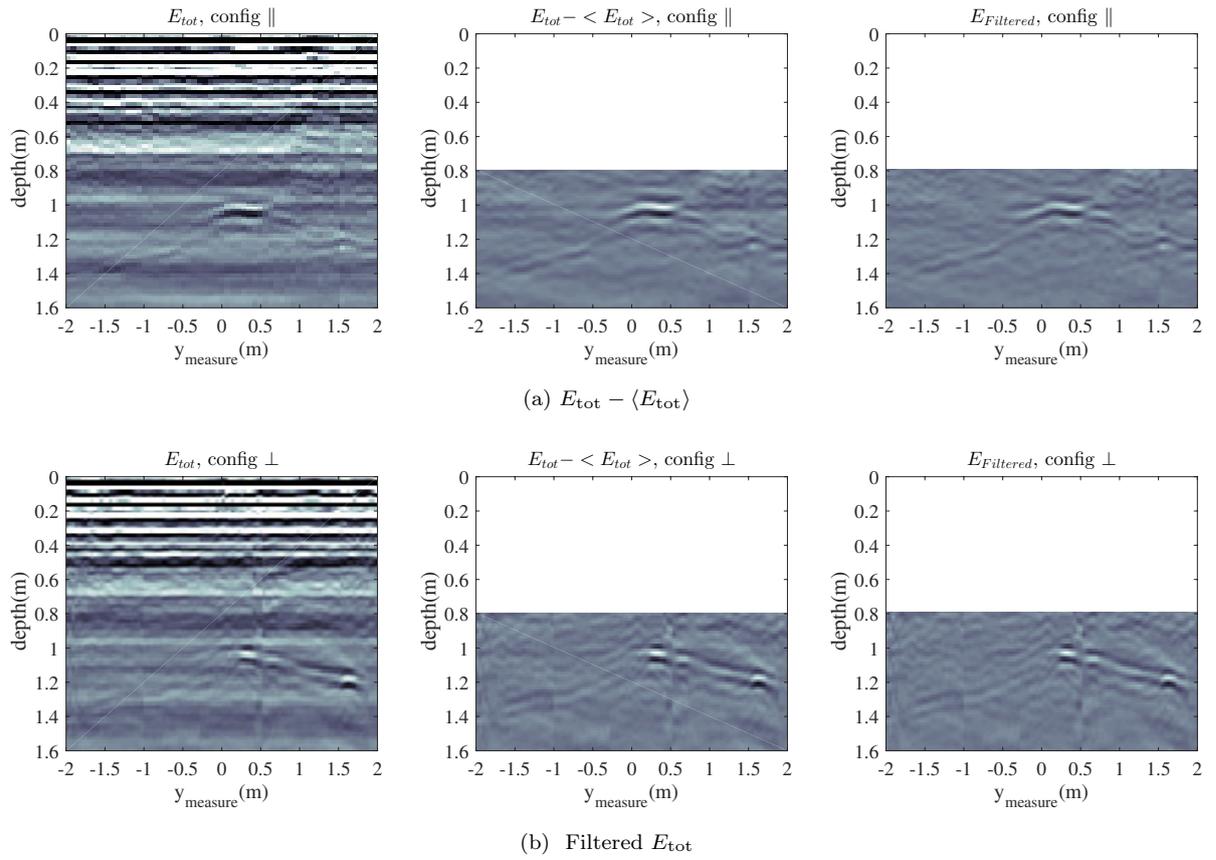

Figure 15: B-scan radargrams of  $E_{tot}$ ,  $E_{tot} - \langle E_{tot} \rangle$  and filtered  $E_{tot}$  corresponding to parallel polarization in (a) and perpendicular polarization in (b).

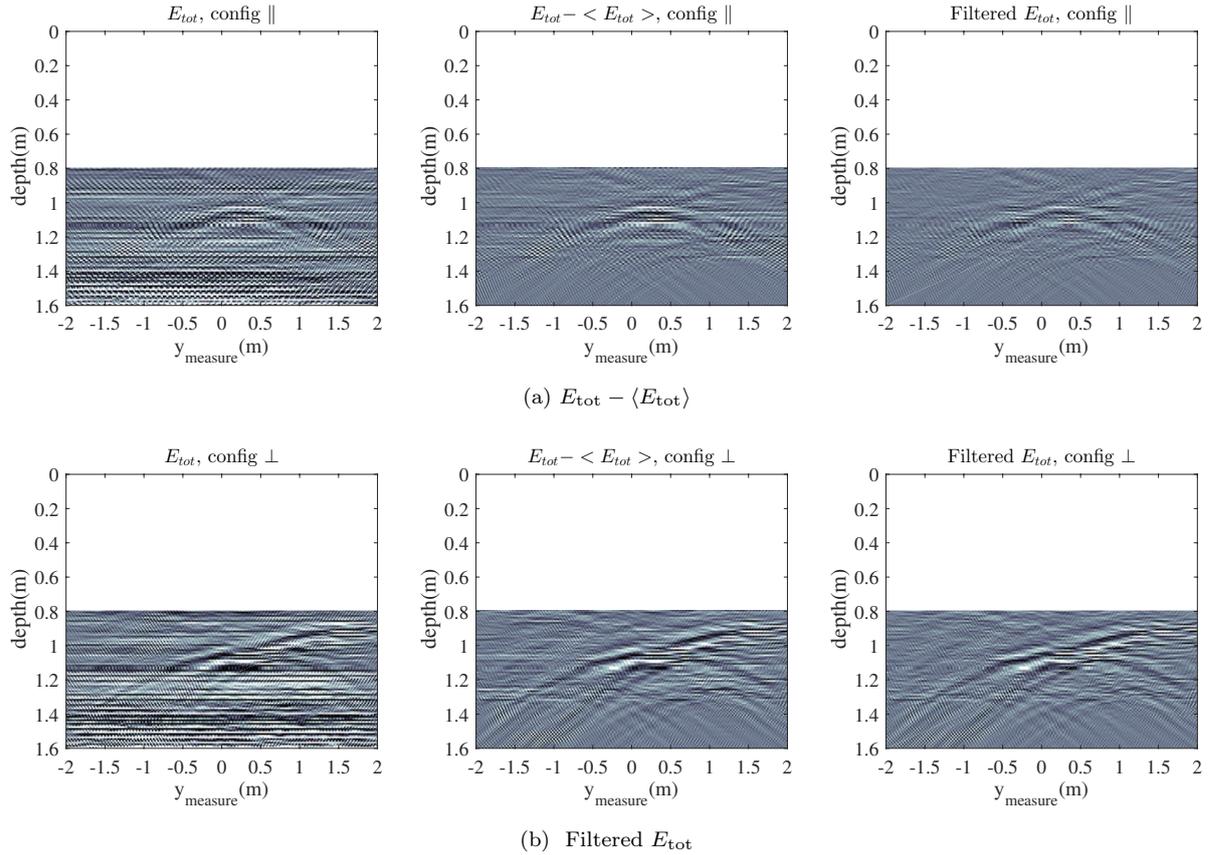

Figure 16: Kirchhoff migration results of  $E_{tot}$ ,  $E_{tot} - \langle E_{tot} \rangle$  and filtered  $E_{tot}$  for parallel (a) and perpendicular (b) configuration.

218 France R&D. Two homogeneous burying environments have been used (wet and dry sands) which is a simplification  
 219 of the real soil. However, the measurement campaign carried out in the actual environment have proved that high  
 220 frequency GPR technique is an efficient tool for the buried cables detection. For the clutter reduction we have  
 221 exploited two different methods that bring the same enhancement to the measured B-scan. Based on experimental  
 222 data collected at the measurement site, the cable is localized if its depth is greater than 0.5 m. Indeed, the clutter  
 223 due to the antenna response ringing and the soil inhomogeneity, engender parasitic oscillation that are hardly  
 224 filtered. For shallowly buried cable, this technique is not efficient. Also, the polarization of the transmitting and  
 225 receiving antennas has been investigated. Parallel polarization is recommended for use since the scattered field is  
 226 higher.

227 From the antenna point of view, the VFBA is bent so the distance between the excitation part of the antenna  
 228 (central part) and the soil is about 7 cm, which helps to keep the antenna matching stable even in front of a wet  
 229 environment. The risk of placing the antenna in front of high conductive medium is that the reflected signal is  
 230 strong enough to mismatch the antenna excitation. Consequently, the energy accepted by the antenna is reduced.

### 231 Acknowledgment

232 This research was carried out within the framework of EU funded COST Action TU1208 Civil Engineering  
 233 Applications of Ground Penetrating Radar. The authors wish to acknowledge the help of Dr. Céline Miry and Dr.  
 234 Emmanuel Amador from EDF R&D for providing us the opportunity to do the measurement at the EDF site.
