## Abstract

In this paper, a novel strategy to generate broad-band earthquake ground motions from the results of 3D physics-based numerical simulations (PBS) is presented. Physics-based simulated ground motions embody a rigorous seismic wave propagation model (i.e., including source-, path- and site- effects), which is however reliable only in the long period range (typically above 0.75 – 1 s), owing to the limitations posed both by computational constraints and by insufficient knowledge of the medium at short wavelengths. To cope with these limitations, the proposed approach makes use of Artificial Neural Networks (ANN), trained on a set of strong motion records, to predict the response spectral ordinates at short periods. The essence of the procedure is, first, to use the trained ANN to estimate the short period response spectral ordinates using as input the long period ones obtained by the PBS, and, then, to enrich the PBS time-histories at short periods by scaling iteratively their Fourier spectrum, with no phase change, until their response spectrum matches the ANN target spectrum. After several validation checks of the accuracy of the ANN predictions, the case study of the M6.0 Po Plain earthquake of May 29, 2012 is illustrated as a comprehensive example of application of the proposed procedure. The capability of the proposed approach to reproduce in a realistic way the engineering features of earthquake ground motion, including the peak values and their spatial correlation structure, is successfully proved.

## Introduction

30  
31 Earthquake ground motion prediction tools underwent a major development in the recent years,  
32 mainly because of the increasing number of strong motion records, especially in the near-field of  
33 important earthquakes. This contributed to expand research on ground motion prediction equations  
34 (GMPEs), i.e., the empirical models providing peak values of ground motion across the entire  
35 frequency band of engineering interest, as a function of magnitude, of suitable measures of source-  
36 to-site distance and of site conditions.

37 Due to simplicity and to limited computational cost, GMPEs are among the most important  
38 ingredients of seismic hazard assessment. However, despite their overall effectiveness and ease-  
39 of-use, the practical application of GMPEs presents several important shortcomings: (i) they  
40 provide only peak values of motion, whereas the use of non-linear time history analyses requiring  
41 reliable input motions is becoming more and more relevant within many applications of  
42 performance-based seismic design; (ii) although their number is continuously growing, the  
43 available records to calibrate a GMPE are still too few to cover the variety of situations, in terms  
44 of combinations of magnitude, distance, fault slip distribution, directivity, and shallow geological  
45 condition, which may cause a significant variability of ground motions in terms of amplitude,  
46 duration and frequency content; (iii) the data-driven calibration of GMPEs implies that the  
47 empirical coefficients vary when calibration datasets are updated; (iv) GMPEs encompass generic  
48 site conditions, represented for instance by means of the average shear velocity in the top 30  
49 meters,  $V_{S30}$ , therefore neglecting the site-specific features, such as surface or buried topographies,  
50 basin edges, irregular soil layering, which may critically change the features of ground motion  
51 with respect to the generic site response; (v) the point-wise prediction by GMPEs cannot reproduce  
52 the spatial correlation structure of the peak values of motion at multiple sites, strongly limiting

53 their use for seismic hazard and risk assessment study at regional scale, such as within large urban  
54 areas. As a matter of fact, in such situations additional models describing the spatial correlation of  
55 ground motion have to be applied to standard GMPEs (see e.g. Jayaram and Baker, 2009; Esposito  
56 and Iervolino, 2012).

57 A variety of procedures was proposed in the past to improve the above limitations of GMPEs and  
58 the accuracy of earthquake ground motion prediction (see Douglas and Aochi, 2008, for a  
59 comprehensive review). Among such procedures, boosted by the ever increasing availability of  
60 parallel high performance computing, 3D physics-based numerical simulations (PBSs) are  
61 becoming one of the leading tools to obtain synthetic ground motion time histories, whose use for  
62 seismic hazard and engineering applications is subject to growing attention and debate (see e.g.  
63 Bradley *et al.*, 2017).

64 Being based on a more or less detailed spatial discretization of the continuum and on the numerical  
65 integration of the seismic wave equation, carried out according to different methods (such as finite  
66 differences, finite elements or spectral elements), PBSs require a sufficiently detailed model of the  
67 seismic source, of the propagation path, and of the Earth crustal layers. To enjoy the effectiveness  
68 of semi-analytical solutions of elastic wave propagation, the shallow Earth's structure is often  
69 modelled as a system of horizontal layers (see e.g. Spudich and Xu, 2002; Hisada and Bielak,  
70 2003). In this paper, we will refer only to those approaches where 3D numerical models of the  
71 shallow geological layers can be considered.

72 Physics-based numerical modeling already proved in the recent past to be well suited for global  
73 (Graves, 1996; Wald and Graves, 1998; Pitarka *et al.*, 1998; Komatitsch and Tromp, 2002a,b) and  
74 regional scale simulations (Bao *et al.*, 1998; Olsen, 2000; Dumbser and Käser, 2006; Day *et al.*,  
75 2008; Tsuda *et al.*, 2011; Smerzini and Villani, 2012; Taborda and Bielak, 2014; Villani *et al.*,

76 2014; Paolucci *et al.*, 2015; Chaljub *et al.*, 2015; Gatti *et al.*, 2017), making potentially feasible  
77 the challenging problem of a multi-scale simulation from the seismic source to the structural  
78 response within a single computational model (Mazzieri *et al.*, 2013; Isbiliroglu *et al.*, 2015).  
79 Typically, PBSs are based either on a kinematic description of the co-seismic slip distribution  
80 model or on a spontaneous dynamic rupture process. Spatially correlated random field models of  
81 slip function parameters (e.g., Herrero and Bernard, 1994; Mai and Beroza, 2003; Crempien and  
82 Archuleta, 2015; Anderson, 2015) are often considered to provide a realistic level of complexity  
83 of the generated seismic wavefield and enhance its frequency content within physical constraints  
84 from seismological observations. However, even in the presence of an ideal seismic source model,  
85 exciting the whole frequency spectrum, the accuracy of the PBS in the high-frequency range is  
86 limited, on the one hand, by the increased computational burden as the mesh gets finer, and, on  
87 the other hand, by the lack of detailed knowledge to construct a geological model with sufficient  
88 details also at short wavelengths, especially for complex configurations. As a result, accuracy  
89 achieved by PBS is usually bounded up to 1 – 1.5 Hz, although some examples of higher frequency  
90 ranges covered by deterministic PBS, with good performance validations against records, have  
91 also been published (e.g., Smerzini and Villani, 2012, modeling the M6.3 L’Aquila near-source  
92 earthquake ground motion up to 2.5 Hz; Taborda and Bielak, 2014, modeling the M5.4 Chino Hills  
93 earthquake up to 4 Hz, Maufroy *et al.*, 2015, simulating a sequence of small earthquakes in the  
94 Volvi basin, Greece, up to 4 Hz).  
95 Different recent research works have addressed the high-frequency limitation of PBS, such as in  
96 the framework of the Southern California Earthquake Center (SCEC) Broadband Platform, aiming  
97 to extend the frequency band of synthetics and to enable PBS to be used with confidence in  
98 engineering applications (see Goulet *et al.*, 2015). Broad-band (BB) waveforms are generally

99 produced by a hybrid approach combining low-frequency results from deterministic PBS with  
100 high-frequency signals from stochastic approaches, typically through either point- or finite-source  
101 methods (e.g., Boore, 2003; Motazedian and Atkinson, 2005) or stochastic Green's function  
102 methods (e.g., Kamae *et al.*, 1998; Mai *et al.*, 2010). Hybrid waveforms are then obtained by gluing  
103 the low-frequency and high-frequency portions of the spectrum with amplitude and phase  
104 matching algorithms (e.g., Mai and Beroza, 2003). Table 1 lists a sample of recently published  
105 studies of BB earthquake ground motions based on coupling low-frequency 3D PBS with high-  
106 frequency stochastic contributions.

107 Although it has been applied to many case studies worldwide, the hybrid approach may have some  
108 basic drawbacks, which prevent its use especially for regional applications: (i) typically, the low  
109 (from PBS) and high (from stochastic) frequency parts turn out to be poorly correlated, being  
110 generated through independent methods with different assumptions regarding the source and the  
111 propagation medium; (ii) the low and high frequency seismograms are combined around a cross-  
112 over frequency  $f_c$ , where the corresponding Fourier spectra are multiplied by weighting functions  
113 and summed up. Such operation may result in a Fourier spectrum of the hybrid broadband ground  
114 motion presenting artificial holes around the cross-over frequency and, to overcome this issue,  
115 may require a site-specific calibration of  $f_c$  (see e.g. Ameri *et al.*, 2012).

116 In this paper we propose a novel approach to generate BB ground motions, which couples the  
117 results of PBS for a specific earthquake ground motion scenario with the predictions of an  
118 Artificial Neural Network (ANN), overcoming some of the main issues of hybrid modeling. The  
119 basic steps of the procedure can be summarized as follows: (1) the ANN is trained on a strong  
120 motion dataset, to correlate short-period ( $T \leq T^*$ ) spectral ordinates with the long period ones  
121 ( $T > T^*$ ), being  $T^*$  the threshold period beyond which results of the PBS are supposed to be accurate;

122 (2) the trained ANN is used to obtain the short period spectral ordinates of the physics-based  
123 earthquake ground motion for periods below  $T^*$  (Figure 1); (3) the PBS long period time histories  
124 are enriched at high frequencies with an iterative spectral matching approach, until the response  
125 spectrum matches the short period part obtained by the ANN.

126 A detailed introduction of the procedure, denoted hereafter by ANN2BB, is given in the following  
127 chapters, with an application example to the PBS obtained for the  $M_w$ 6.0 Po Plain earthquake of  
128 May 29, 2012 (Paolucci *et al.*, 2015), for which a comprehensive validation exercise can be made,  
129 based on more than 30 strong motion records obtained at less than 30 km epicentral distance. Such  
130 validation aims at encompassing different key aspects to evaluate the applicability of physics-  
131 based earthquake ground motion to engineering practice, not only in terms of the high-frequency  
132 content and of the proper attenuation of peak values with distance, but also in terms of the  
133 verification of the spatial correlation of peak ground motion values.

## 134 **Correlation of long and short period spectral ordinates through an ANN**

### 135 **trained on a strong motion dataset**

#### 136 **Design and training of an ANN**

137 Artificial Neural Networks are generally used to estimate the non-linear relationship between a  
138 highly populated vector of input variables and a vector of output unknowns, for the correlation of  
139 which fast and closed-form rules cannot easily be applied. As a matter of fact, under mild  
140 mathematical conditions, any problem involving a continuous mapping between vector spaces can  
141 be approximated to arbitrary precision (i.e. within an error tolerance) by *feed-forward* ANNs which  
142 is the most often used type (Cybenko, 1989). Our purpose is to establish through the ANN a  
143 correlation between  $N_{Sa}^{LP}$  long period response spectral ordinates selected for  $T \geq T^*$ , being  $T^*$  the

144 threshold period corresponding to the range of validity of PBS, with  $N_{S_a}^{SP}$  short period response  
145 spectral ordinates for  $T < T^*$ . A high-quality strong ground motion dataset (denoted in the  
146 following by SIMBAD, see Smerzini *et al.*, 2014 for details) was used for training. SIMBAD  
147 consists of  $N_{ab} \sim 500$  three components records from about 130 shallow crustal earthquakes  
148 worldwide, roughly homogeneously distributed in the  $M_W$  range from 5 to 7.3 and epicentral  
149 distance  $R_{epi} < 35$  km. Quantitative information on site characterization, preferably in terms of  
150  $V_{S30}$ , is available for all stations.

151 Two separate ANNs are considered and trained independently, one referring to the geometric mean  
152 of the horizontal components and one to the vertical one. As long as the database is updated with  
153 new strong motion records, the procedure can ideally be extended by training different ANNs  
154 separately, for different homogeneous datasets (such as for different soil classes) and/or for  
155 different components of motion (such as fault normal and fault parallel). In our case, the neural  
156 network is designed as a two-layers (i.e. nodes are grouped in layers) feed-forward (i.e. the arcs  
157 joining nodes are unidirectional, and there are no cycles) neural network with  $N_n^h$  sigmoid hidden  
158 neurons (the so-called activation functions) and a linear output neuron. The number of nodes in  
159 the input layer  $N_n^i$  equals the number of input variables  $N_{S_a}^{LP}$ . The number of nodes in the output  
160 layer  $N_n^o$  equals the number of target values  $N_{S_a}^{SP}$ . With this kind of configuration, the ANN takes  
161 the name of Multi Layer Perceptron (Bishop, 1995; Bishop and Roach, 1992). The  
162 backpropagation of error was used in the training phase (McClelland *et al.*, 1986). The idea is to  
163 propagate the error signal, computed in single teaching step, back to all connected neurons. Back-  
164 propagation needs a *teacher* that knows the correct output for any input (supervised learning) and  
165 uses gradient descent methods (Levenberg, 1944; Marquardt, 1963) on the error to train the  
166 weights. In this work, a built-in neural network fitting tool available in Matlab, namely the package

167 *nftool*, was used. The *nftool* package solves the problem of data fitting using a two-layer feed-  
168 forward network trained with the Levenberg-Marquardt algorithm. A simplified sketch of the logic  
169 scheme at the basis of the ANN training process is shown in Figure 2.

170 Referring to Figures 1 and 2, the  $N_{Sa}^{LP}$  input parameters are  $\{\log_{10}[SA(T_j)]\}_{j=1}^{N_{Sa}^{LP}}$ , where  $SA$  is  
171 the acceleration response spectral ordinates at period  $T_j$ , ranging from the corner period  $T^*$  (grey  
172 line in Figure 1) to 5 s. The outputs are  $N_{Sa}^{SP}$  ground motion parameters, specifically,  
173  $\{\log_{10}[SA(T_k)]\}_{k=1}^{N_{Sa}^{SP}}$ , at periods  $T_k = 0$  (i.e.  $PGA =$  Peak Ground Acceleration), up to  $T^*$ . Note  
174 that the ANN is designed to predict multiple outputs given multiple inputs: specifically,  
175 considering  $T^*=0.75$  s, as in this study, the number of outputs and inputs is 20 and 9, respectively,  
176 with a sampling equal to  $T_j = [0.75,0.8:0.1:1.0,1.25:0.25:5.0]$  s for the input and of  $T_k =$   
177  $[0,0.05,0.1:0.1:0.7]$  s. In such conditions, two common sets of weights  $w$  and biases  $b$  are  
178 iteratively adjusted to map the input to the hidden layer, as well as the hidden layer to the output  
179 layer.

180 As for the training of the ANN, the adopted scheme is based on the random subdivision of the  
181 entire dataset of  $N_{db}$  input-output data into three subsets (as implemented in Matlab *nftool*): (1) a  
182 training set, used to calibrate the adjustable ANN weights; (2) a validation set, made of patterns  
183 different from those of the training set and thus used to monitor the accuracy of the ANN model  
184 during the training procedure; (3) a test set, not used during ANN training and validation, but  
185 needed to evaluate the network capability of generalization in the presence of new data. This  
186 distinction helps limiting the problem of overfitting, which is a well-known shortcoming of ANN  
187 design. As a matter of fact, even though the error on the training set is driven to a very small value,  
188 the network may fail in generalizing the learned training patterns if the patterns of the training set  
189 do not sufficiently cover the variety of new situations. An *early stop* criterion was adopted to stop

190 the training phase when the error on the validation set starts growing. In our computations, the  
191 training/validation/testing sets were set to 85%/10%/5%. More specifically, before selecting the  
192 final network, different ANNs were constructed, for a total of  $N_{train} = 50$ , each based on a  
193 different training subset randomly extracted among 95% of the records. The final ANN was  
194 selected as the one providing the best performance, i.e., the lowest mean square error on the  
195 remaining 5% of the dataset.

196 A number of hidden neurons  $N_n^h = 30$  was assumed, after a parametric analysis proving that this  
197 number provides a reasonable compromise in terms of accuracy of the network (see for details  
198 Gatti, 2017).

### 199 200 **Testing the ANN performance**

201 The performance of the selected ANN in predicting the actual recordings has been evaluated by  
202 computing the logarithmic residuals of the response spectral ordinates predicted by the ANN  
203 ( $SA_{ANN}$ ) with respect to the observed ones from SIMBAD dataset ( $SA_{Obs}$ ), i.e.  $\log_{10}(SA_{ANN}/SA_{Obs})$ .  
204 Figure 3 illustrates the residual bars corresponding to  $\pm 1\sigma$  for the geometric mean of horizontal  
205 components, as a function of  $T/T^*$ , for different values of  $T^*$ , corresponding to different possible  
206 intervals of validity of the PBS results, namely  $T^*=0.50$ s (left panel), 0.75 s (center) and 1.0 s  
207 (right). The number of input and output parameters ( $N_{Sa}^{LP}, N_{Sa}^{SP}$ ) in the three cases are (22,6), (20,9)  
208 and (17, 11), respectively. Results are shown and compared for the training, validation and test  
209 phases. It is shown that, in terms of normalized period, performance is similar for the different  
210 values of  $T^*$ , with an obvious tendency of larger uncertainties as period gets lower, being more  
211 distant than the corner period  $T^*$ . In spite of this effect, it is noted that typically the accuracy of  
212  $PGA$  prediction is higher. When expressed in non-normalized terms, the lower is  $T^*$  the more  
213 accurate is the prediction. It is worth underling that, with few exceptions, the error of both the

214 validation and test phases is bounded to  $\pm 0.3$  in  $\log_{10}$  scale (i.e., a factor of 2), which corresponds  
215 incidentally to the total standard deviation,  $\sigma_{\log_{10}}$ , of typical GMPEs (see e.g. Cauzzi *et al.* 2015  
216 derived on a similar database). This suggests that, with respect to standard empirical approaches,  
217 the reduction of uncertainty is improved as the period gets close to  $T^*$ .

218 A similar exercise was made for training, validating and testing an ANN to predict short period  
219 vertical spectral ordinates, based on the same dataset. Results are shown in Figure 4 and denote,  
220 as expected, a slightly worst performance of the vertical ANN with respect to the horizontal one,  
221 owing to the generally poor correlation of short vs long period spectral ordinates of vertical ground  
222 motions. This is clear especially for the ANN trained for  $T^*=1$  s, with error bars of the validation  
223 and testing phases exceeding a factor of 3 (i.e., 0.5 in  $\log_{10}$  scale) and with a significant bias on  
224 the negative side, showing that, for both the validation and test datasets, the ANN predictions  
225 underestimate significantly the observations. However, results get significantly better when  
226 decreasing  $T^*$  and, already with  $T^* = 0.75$  s, the error bars do not exceed a factor 0.4 in  $\log_{10}$  scale  
227 and the bias is significantly reduced.

228 Note that the previous horizontal and vertical ANNs were trained on a dataset (about 500 three-  
229 component waveforms), containing strong motion records within relatively limited epicentral  
230 distance and magnitude ranges. For this reason, we did not find a significant improvement on the  
231 results when distance and magnitude were considered as additional input parameters of the training  
232 phase, as it could be in case of training of more general ANNs on wider record datasets. On the  
233 other hand, more specific ANNs may be trained on subsets of records, aiming for example at  
234 distinguishing between soft and stiff soil conditions and, hence, at providing improved accuracy  
235 for site-specific evaluations. A check was made with such objective, as documented in Gatti  
236 (2017), but only a slight decrease of performance was found with respect to the ANN trained on

237 the complete dataset, as if the improved classification of records was not sufficient to balance the  
238 significant decrease of number of records for each ANN. As a final remark, although we did not  
239 make quantitative tests on the minimum number of records needed for robust estimates, our  
240 performance checks indicate that stable results are obtained only within the magnitude and distance  
241 ranges of the dataset, and extrapolation out of such ranges is not reliable.

### 242 **The ANN2BB procedure to produce broad-band strong ground motions from** 243 **3D physics-based numerical simulations**

244 Based on the tests illustrated in the previous section, different ANNs may be trained for different  
245 values of  $T^*$ , related to the frequency resolution of the numerical model (in this application,  
246  $T^*=0.75$  s is considered). Therefore, this first step allows one to compute, for all PBS with range  
247 of validity  $T>T^*$ , a site-specific ANN-based broad-band response spectrum, denoted in the  
248 following by ANN2BB, as well as maps of peak values of short period ground motion. Note that,  
249 at this stage, such BB response spectrum does not correspond to a specific waveform.

250 To obtain BB time histories from the ANN2BB spectra, a spectral matching approach is used,  
251 similar to those adopted in the engineering practice to adapt a real accelerogram to a prescribed  
252 target spectrum (NIST, 2011), where the record is iteratively scaled either in the frequency domain  
253 (see e.g. Shahbazian and Pezeshk, 2010) or by wavelet transforms (e.g. Atik and Abrahamson,  
254 2010), with no phase change, until its response spectrum approaches the target within a given  
255 tolerance. In our case, instead of a recorded accelerogram, we consider the time history resulting  
256 from the physics-based simulation, and, as a target, the ANN2BB spectrum. In this work we  
257 selected the scaling in the frequency domain, but other spectral matching procedures can obviously  
258 be used.

259 The difficulty, with respect to the standard spectral matching approach, comes from the low-  
260 frequency band-limited nature of the simulated time-history, which implies that the high-frequency  
261 content of the waveform, essentially consisting of numerical noise, is not usable for scaling. To  
262 overcome this issue, before spectral matching to the desired target ANN2BB spectrum, the high-  
263 frequency portion of the simulated waveform was enriched by a stochastic component, by gluing  
264 the low and high-frequency parts with the procedure described in Smerzini and Villani (2012). For  
265 high-frequency signals, we successfully tested both the Sabetta and Pugliese (1996) and the Boore  
266 (2003) approaches, the latter implemented in the code EXSIM (Motazedian and Atkinson, 2005),  
267 and selected the result providing the best fit to the target ANN2BB spectrum. Note that, as spectral  
268 matching is achieved by scaling only amplitudes, the high-frequency random phases generated in  
269 the hybrid step are maintained.

270 To summarize, the main steps of the ANN2BB procedure are the following:

- 271 1) an earthquake ground motion scenario is produced based on 3D PBS, whose accuracy in terms  
272 of response spectral ordinates is limited to  $T \geq T^*$ , owing to mesh discretization issues as well  
273 as to limited information on the geological models;
- 274 2) an ANN is trained based on a strong motion records dataset to predict short period spectral  
275 ordinates ( $T < T^*$ ) based on long period ones ( $T \geq T^*$ );
- 276 3) for each simulated waveform, a ANN2BB response spectrum is computed, the spectral  
277 ordinates of which, for  $T \geq T^*$ , coincide with the simulated ones, while, for  $T < T^*$ , they are  
278 obtained from the ANN. Both horizontal and vertical components can be obtained, although  
279 with a lower level of accuracy for the vertical case;
- 280 4) the simulated low-frequency waveform is enriched in the high-frequency by a stochastic  
281 contribution, characterized by the magnitude and source-to-site distance of the scenario

282 earthquake under consideration;

283 5) the hybrid PBS-stochastic waveform is iteratively modified in the frequency domain, with no  
284 phase change, until its response spectrum matches the target ANN2BB spectrum.

## 285 **A case study: broad-band ground motions from the numerical simulations of** 286 **the May 29 2012 Po Plain earthquake**

287 To test the proposed approach for the generation of BB ground motions and to verify the accuracy  
288 of results against observations during recent earthquakes, we considered as a case study the  
289 numerical simulation of the Mw6 May 29 2012 Po Plain earthquake, Northern Italy. This  
290 earthquake is very meaningful for validation purposes, because of the availability of a significant  
291 number of near-source strong-motion records, some of which obtained at very short inter-station  
292 distances, as well as of the good knowledge on the complex geologic setting of the Po Plain, which  
293 enabled the construction of a robust 3D numerical model including its complex buried  
294 morphology. 3D physics-based numerical modelling of ground shaking during the May 29 2012  
295 Po Plain earthquake, has been addressed in a previous work (Paolucci *et al.*, 2015), where the  
296 validation of simulated ground motions against recordings has been thoroughly analysed and  
297 discussed, limited to the frequency range of design of the numerical mesh.

298 We aim herein at extending the validation to the simulated BB ground motions, encompassing  
299 several aspects of engineering relevance, from the comparison of BB simulated with records at  
300 selected near-source sites, as well as the spatial distribution of peak values of ground motion and  
301 their spatial correlation features.

## 302 **Review of the case study and main results**

303 On May 20 and 29 2012, two earthquakes with moment magnitude  $M_w$  of 6.1 and 6, respectively,  
304 occurred in the Po Plain region, Northern Italy, along a thrust fault system with a nearly East-West  
305 strike and dipping to the South (Luzi *et al.* 2013). The May 29 earthquake was extensively recorded  
306 by several accelerometric networks, making available a unique dataset of high-quality strong-  
307 motion recordings in the near-source region of a major thrust event and within a deep soft sediment  
308 basin structure like the Po Plain. More than 30 recordings are available at epicentral distances less  
309 than 30 km and have been the basis for the validation of the 3D PBSs.

310 Referring to Paolucci *et al.* (2015) for a detailed description of the spectral-element model, we  
311 limit herein to underline its main features. The model, with an extension of about 74 km x 51 km  
312 x 20 km, can propagate up to about 1.5 Hz and includes the following distinctive elements: (i) an  
313 *ad hoc* calibrated kinematic source model of the Mirandola fault with a major slip asperity in the  
314 up-dip direction; (ii) the 3D velocity model of the Po Plain which accounts for the pronounced  
315 irregularity of the base of Quaternary sediments, with thickness varying abruptly in a short distance  
316 range from few tens of m in the epicentral area down to several km; (iii) a linear visco-elastic soil  
317 model, with frequency proportional quality factor  $Q$ .

318 The numerical model was found to predict with satisfactory accuracy, measured through  
319 quantitative goodness-of-fit criteria, the most salient features of near-source ground motion, such  
320 as, in particular, (i) the strong up-dip directivity effects leading to large fault-normal velocity  
321 pulses, (ii) the small-scale variability at short distance from the source, resulting in the out-of-  
322 phase motion at stations separated by only 3 km distance, (iii) the prominent trains of surface  
323 waves propagating with larger amplitudes in the Northern direction and dominating ground motion  
324 already at some 10 km distance from the epicenter, (iv) the spatial distribution of ground uplift on  
325 the hanging wall of the fault, in substantial agreement with geodetic measurements, (v) the

326 macroseismic intensity distribution.

### 327 **Maps of peak values of ground motion**

328 The validation checks quoted in the previous section, and reported in detail by Paolucci *et al.*  
329 (2015), were limited to information extracted from the numerical results up to about 1.5 Hz, i.e.,  
330 the range of validity of the PBS. We consider now additional tests, based on the BB results  
331 obtained with the ANN2BB procedure outlined previously.

332 The spatial variability of peak values of ground motion is first addressed and compared with  
333 available observations. To this end, Figure 5 compares the maps of simulated *PGA* (geometric  
334 mean of horizontal components) obtained by (a) the ANN2BB procedure (steps 1 to 5 of the  
335 previous section), (b) the hybrid PBS-stochastic approach (steps 1 to 4) and (c) the PBS results  
336 filtered at 1.5 Hz (only step 1). The Sabetta and Pugliese (1996) approach was considered to  
337 produce the stochastic high-frequency portion of motion at step 4. On the same maps of Figure 5,  
338 the values of recorded *PGA* are also superimposed, taken from processed ITACA waveforms. In  
339 Figure 5d, recorded and simulated (ANN2BB) horizontal *PGA* values are shown as a function of  
340 the Joyner-Boore distance,  $R_{JB}$ , and compared with the GMPE of Bindi *et al.* (2014), referred to  
341 as BI14. The latter was obtained assuming  $M_W=6.0$ , reverse focal mechanism and  $V_{S30}=220$  m/s.

342 The following observations can be made:

343 - the proposed ANN2BB approach provides high-frequency ground motion predictions correlated  
344 to the low-frequency motion obtained by PBS. This is made evident by the similarity of the spatial  
345 pattern, related to source effects, of Figure 5a (ANN2BB) and Figure 5c (PBS), although PBS  
346 values are bounded because of the low frequency range of the simulations. Furthermore, from the  
347 comparison between the maps at top of Figure 5, it is apparent that the *PGAs* obtained by the  
348 present approach reflect some physical features related to the wave propagation phenomenon itself

349 (directivity, directionality, site conditions, etc.), that are missing from the stochastic approach.  
350 Namely, (i) the larger values of peaks on the northern side of the fault are consistent with the up-  
351 dip directivity effects, (ii) the pronounced NW-SE alignment of the peak corresponds to the  
352 prevailing orientation of the submerged bedrock topography included in the 3D numerical model,  
353 thus giving evidence of a complex 3D site effect, as discussed in more detail by Paolucci *et al.*  
354 (2015);

355 - there is an overall good agreement between the spatial distribution of simulated *PGA* and the  
356 recorded values, although simulations tend to be lower than records. This is consistent with a  
357 similar tendency of underestimation of recorded motions from PBS also in the long period range,  
358 as previously noted by Paolucci *et al.* (2015);

359 - the comparison with the GMPE by BI14 puts in evidence that *PGAs* recorded within the Po Plain  
360 lie well below the median empirical prediction. This can be attributed to the reduction of *PGA*  
361 values that is usually noted at the surface of deep sedimentary basins (Lanzano *et al.*, 2016). It is  
362 also noted that the ANN2BB predicted values are below the GMPE results, consistently with  
363 records, but their decay with distance is faster, probably due to an overestimation of damping  
364 within the shallow soil layers of the numerical model.

### 365 **Comparison between simulated BBs and recordings**

366 Performance of the ANN2BB approach can be evaluated by checking the BB simulated ground  
367 motions. For this purpose, we show in Figure 6, from left to right, the acceleration, velocity and  
368 displacement time histories of the NS component of the Mirandola (MRN) station, located at an  
369 epicentral distance of 4 km, in one of the areas mostly affected by the earthquake. From top to  
370 bottom, the figure shows in sequence the result of PBS, according to Paolucci *et al.* (2015), the  
371 stochastic waveform (STO) obtained using the Sabetta and Pugliese (1996) approach, the hybrid

372 (HYB) waveform obtained by combining PBS at low-frequency and STO at high-frequency,  
373 having selected 1.5 Hz as the cross-over frequency for gluing the low and high-frequency parts,  
374 the ANN2BB waveform obtained by scaling HYB to the target response spectrum based on the  
375 application of ANN to the PBS spectral ordinates. The last row of Figure 6 portrays the recorded  
376 (REC) waveform. Comparison is further clarified in Figure 7, in terms of response spectra (left)  
377 and Fourier spectra (right) of the waveforms in Figure 6.

378 It turns out that both the HYB and the ANN2BB waveforms provide a remarkable approximation  
379 of recorded ground motion, both in time and frequency domain, enjoying for the MRN station a  
380 very good performance of the PBS at long periods, as confirmed by comparison with a larger set  
381 of stations, at different distances and azimuths (Figure 8). From this comparison, it is noted that  
382 the performance of ANN2BB is less satisfactory at those sites (e.g. MOG0) where the PBS results  
383 at long periods do not fit closely the observed values.

384 The main advantage of ANN2BB vs HYB is that the high-frequency part is related through the  
385 ANN to the low-frequency one: therefore, as illustrated in the next section, a good agreement is  
386 also expected in terms of the spatial correlation of peak values of ground motion.

### 387 **Spatial correlation of peak values of ground motion**

388 The most important motivation driving the search for a recipe to produce BB from 3D physics-  
389 based simulations using the ANN2BB approach, is that the correlation provided through the ANN  
390 between the low- and high-frequency parts of simulated ground motions is expected to ensure a  
391 realistic spatial correlation of peaks of ground motion also in the high-frequency range, not covered  
392 by the numerical simulations. For this purpose, a standard tool to quantify the spatial variability of  
393 a random process of spatially distributed samples is the semivariogram  $\gamma(h)$  (Webster and Oliver,  
394 2007) measuring, in general terms, the average dissimilarity of data at inter-station distance  $h$ .

395 Taking advantage of the well-known methods to model the spatial correlation between earthquake  
396 ground motion values (see e.g. Jayaram and Baker, 2009; Esposito and Iervolino, 2011; Loth and  
397 Baker, 2013), the semivariogram  $\gamma(h)$  and the corresponding correlation coefficient  $\rho(h)$  (Webster  
398 and Oliver, 2007) can be evaluated through the following steps: (i) computing the semivariogram  
399 by the method of moments (Matheron, 1965) under the hypothesis of second order stationarity,  
400 (iii) selecting the theoretical model of the semivariogram, (iii) estimating the parameters of the  
401 model, referred to as sill (i.e., the variance of the random process) and range (i.e., the inter-station  
402 distance at which  $\gamma(h)$  tends to the sill, indicating that motions are uncorrelated), by fitting the  
403 computed semivariogram values with the functional form chosen at the previous point and (iv)  
404 computing the correlation coefficient as the complementary to the semivariogram normalized by  
405 the sill. Referring to literature studies for the analytical background (Jayaram and Baker, 2009;  
406 Esposito and Iervolino, 2011; 2012), we note that, in this work, the residual terms, on which the  
407 semivariogram is computed, are evaluated with respect to an average trend defined as:

$$408 \quad P(R_{line}) = a + \log_{10}(R_{line} + b) \quad (1)$$

409 where  $P$  is the peak parameter of ground motion of interest (e.g.,  $PGA$ ) and  $R_{line}$  is the closest  
410 distance from the surface fault projection of the segment at the top edge of the rupture plane, which  
411 was found to be the best distance metrics for the Po Plain simulations (Hashemi *et al.*, 2015), as  
412 well as for other case studies of normal and reverse fault earthquakes (Paolucci *et al.*, 2016).  
413 Furthermore,  $a$  and  $b$  are regression coefficients calibrated either on records or on simulated  
414 results.

415 Figure 9 shows the semivariograms as a function of the inter-station distance from both recorded  
416 and simulated ground motions along the NS component at the accelerometric stations illustrated  
417 in Figure 5. Symbols denote the semivariogram values associated with different response spectral

418 ordinates, specifically,  $PGA$ ,  $SA(0.2s)$ ,  $SA(1.0s)$ ,  $SA(2.0s)$ , both for the records (crosses) and for  
419 the BB results simulated either through the ANN2BB procedure (open dots) or the HYB procedure  
420 (filled squares). The functional form chosen to fit the corresponding semivariogram data is the  
421 exponential model (Cressie, 1985), shown by continuous and dashed lines for REC and ANN2BB,  
422 respectively. In analogy with previous studies (see e.g. Jayaram and Baker, 2009; Esposito and  
423 Iervolino, 2011), to provide a better representation at short separation distances, we have decided  
424 to fit manually the semivariograms starting from the least-square estimation. On each subplot of  
425 Figure 9 the values of range resulting from the best-fitting model are indicated. Note that larger  
426 values of the range, i.e., the inter-station distance at which the correlation coefficient drops to zero,  
427 means that correlation is preserved at larger distances.

428 It turns out that the best-fitting exponential models on records and on the ANN2BB results are in  
429 good agreement. In both cases, the value of the range varies between 19 to 25 km, with a relative  
430 error between the two range estimates (i.e. from REC and ANN2BB) bounded between 1% (for  
431  $SA 0.2s$ ) and 20% (for  $PGA$ ). This points out that the ANN2BB approach succeeds in reproducing  
432 accurately the spatial correlation structure of response spectral ordinates even at short periods.  
433 Instead, it is apparent that the application of the HYB procedure produces at short periods (see  
434  $PGA$  and  $SA 0.2s$ ) a semivariogram which is almost flat, thus denoting a zero correlation  
435 coefficient at all interstation distances. As a final remark, it is found that that the trend of ranges  
436 obtained with ANN2BB method is increasing with the vibration period, passing from 20 km for  
437  $PGA$  to 24 km for  $SA 2.0s$ , in agreement with the other research works previously mentioned.

438 Although the Po Plain earthquake considered in this work provided one of the widest set of near-  
439 source records from moderate-to-large earthquakes worldwide, the number of stations has to be  
440 considered limited for the computation of the semivariograms. For this reason, it is not possible to

441 group the stations in order to study possible anisotropies in the features of spatial correlation of  
442 ground motion, because the number of stations in each sub-group would be too small. Instead, this  
443 is possible when using the results of numerical simulations, because the number of receivers may  
444 be made arbitrarily large.

445 Figure 10 shows the correlation models for *PGA*, left, and *SA I.Os*, right, obtained from both  
446 recordings and ANN2BB results. In addition to the results obtained at the accelerometric stations  
447 (solid lines), possible anisotropy patterns have been investigated by considering a sufficiently large  
448 set of synthetic receivers located in the Northern and Southern sector with respect to the fault at  
449 distances  $R_{line}$  lower than 10 km (N and S set, respectively). This figure points out an interesting  
450 feature of the ANN2BB simulated waveforms: when considering only receivers with  $R_{line} < 10$   
451 km, both in the North and South direction, spatial correlation drops to 0 faster than when the whole  
452 set of receivers is considered (i.e., correlation distances are significantly shorter). This is very clear  
453 in the intermediate-to-long period range (see e.g. right side of Figure 10, referring to  $T = 1s$ ), while  
454 this trend is less evident at short periods (see left side of the figure, referring to *PGA*), although it  
455 still appears for the receivers lying on the surface fault projection (Figure 10, left subplot, for  $R_{line}$   
456  $< 10$  km, Southern side).

457 It can be concluded that such spatial anisotropy features of peak values of earthquake ground  
458 motion are mainly related to near-source effects. More specifically, proximity to the extended  
459 seismic source produces a faster decay of spatial correlation at very short distances, owing to the  
460 small-scale spatial variability of ground motion induced by the heterogeneous fault rupture  
461 combined with complex site effects related to the approximately NS orientation of the submerged  
462 bedrock topography.

463

## Conclusions

464 In this paper we introduced the ANN2BB procedure, suitable to create realistic BB waveforms  
465 from 3D physics-based numerical simulations. It turns out that the performance of this procedure  
466 is rather good, provided that the simulations are accurate within a frequency band at least extended  
467 to approximately 1.5 Hz, roughly corresponding to  $T^* = 0.75$ s. In such range, the ANN trained to  
468 correlate long period response spectral ordinates ( $T \geq T^*$ ) with those at short periods, was found  
469 to provide satisfactory results. The ANN used in this work was trained on a strong motion dataset  
470 consisting of about 500 records with moment magnitude from 5 to 7.3 and epicentral distance up  
471 to 35 km, but other ANNs can be trained with a similar purpose on wider datasets. Separate ANNs  
472 were trained on the geometric mean of the horizontal components and on the vertical components  
473 to allow the prediction of three-component ground motions.

474 An extension of the training dataset is planned to encompass a wider range of magnitude, distance  
475 and site conditions. Furthermore, since all ANNs considered in this work are deterministic, i.e.,  
476 for one set of input spectral ordinates at long period, a single set of output spectral ordinates at  
477 short period is provided, the training of stochastic ANNs is also envisioned, by defining weights  
478 and biases as random variables.

479 As a comprehensive validation benchmark, we considered the strong motion records obtained in  
480 the near-source region of the May 29, 2012 Po Plain earthquake and the corresponding 3D physics-  
481 based numerical simulations carried out by the spectral element code SPEED and illustrated in  
482 detail in Paolucci *et al.* (2015). Compared to a standard hybrid approach to produce BB waveforms,  
483 consisting of enriching the high-frequency portion of ground motion by a stochastic contribution,  
484 the proposed ANN2BB procedure allows one to obtain a similar realistic aspect of the waveform,  
485 both in time and frequency domains, but, in addition, it also allows one to obtain maps of short-  
486 period peak values of ground motion which reproduce more closely the coupling of source-related

487 and site-related features of earthquake ground motion. And, as a further important asset of the  
488 proposed procedure, as also illustrated by a similar application in Thessaloniki (Smerzini and  
489 Pitilakis, 2017), it is suitable to portray in a realistic way the spatial correlation features of the peak  
490 values of ground motion also at short periods, with the possibility to point out possible spatial  
491 anisotropies, typically related to the near-source or complex geology conditions.

492 To conclude, we remark that, while the correlation structure of the high-frequency peak values is  
493 simulated in a satisfactory way, the procedure is not suitable yet to obtain sets of waveforms with  
494 realistic spatial coherency features at high-frequency (measured in terms of the coherency  
495 operator, see Zerva, 2009), apt for use as input motions for seismic analyses of spatially extended  
496 structures. As a matter of fact, the high-frequency stochastic contributions added to the simulated  
497 motions need to be re-phased to reproduce properly travelling waveforms. This is probably the  
498 single major limitation still existing preventing yet to provide simulated BBs fulfilling all the  
499 characteristics of a real earthquake ground motion wavefield.

## List of Figure Captions

732 **Figure 1.** Main idea behind the proposed ANN-based approach to generate BB ground motions:

733 for a given ground motion, response spectral ordinates at short periods, i.e., for periods  $T \leq T^*$ ,

734 where  $T^*$  is the minimum period of validity of the physics-based numerical model, are computed

735 from the 3D physics-based simulated response spectral ordinates at long periods.

736 **Figure 2.** Logic scheme of the ANN training patterns: the long period spectral ordinates (in this

737 case  $T^* = 0.75$  s) represent the teaching inputs, whereas the short period ones are the outputs

738 predicted by the ANN. The number of neurons in the hidden layer is  $N_n^h = 30$ .

739 **Figure 3.** ANN performance in predicting the horizontal components of SIMBAD records

740 (geometric mean of horizontal components), expressed in terms of  $\log_{10}(SA_{ANN}/SA_{Obs})$ , where

741  $SA_{ANN}$  denotes the response spectral ordinates predicted by the ANN and  $SA_{Obs}$  is the observed

742 ones. The performance is estimated at each vibration period  $T$ , here normalized with respect to the

743 corner period  $T^*$ . The error bars refer to the training (TRN), validation (VLD) and test (TST) set.

744 **Figure 4.** Same as Figure 3, but for the ANN trained on the vertical components of records of the

745 SIMBAD dataset.

746 **Figure 5.** Map of  $PGA$  (geometric mean of horizontal components) obtained by a) the proposed

747 ANN2BB approach, b) the hybrid (HYB) approach by combining the PBS with the stochastic

748 signals from the Sabetta and Pugliese (1996) method, c) the PBS filtered at 1.5 Hz. The filled dots

749 superimposed on each map denote the  $PGA$  values recorded by the available strong-motion

750 stations. d) ANN2BB simulated vs recorded values of  $PGA$  as a function of the Joyner-Boore

751 distance,  $R_{JB}$ , in comparison with the GMPE of Bindi *et al.* (2014), BI14.

752 **Figure 6.** From left to right, acceleration, velocity and displacement time histories of NS

753 component at Mirandola (MRN) station, 29 May 2012 Po Plain earthquake. From the top to the  
754 bottom the subpanels show: (i) the physics based numerical simulation (PBS) filtered with  $f_c = 1.5$   
755 Hz; (ii) stochastic waveform (STO) according to Sabetta and Pugliese (1996); (iii) hybrid  
756 synthetics (HYB) obtained by coupling PBS at low frequency and STO at high frequency with a  
757 cross-over frequency of  $f_c = 1.5$  Hz; (iv) BB synthetics (ANN2BB) resulting by scaling the HYB  
758 upon the ANN-based short-period spectral ordinates; (v) records (REC).

759 **Figure 7.** Same comparison as in Figure 6 but in terms of acceleration response (left) and Fourier  
760 Spectra (right) of NS component at Mirandola (MRN) station.

761 **Figure 8.** 2012 Po Plain earthquake simulation: comparison between ANN2BB simulations and  
762 recordings at four accelerometric stations (MIR08, T0802, BON0 and MOG0) in terms of NS  
763 acceleration and velocity time histories (top panels) and acceleration response spectra (bottom).  
764 The location of the selected stations is shown in Figure 5.

765 **Figure 9.** Semivariograms obtained using records REC (crosses) and the ANN2BB approach  
766 (circle) for *PGA* (top left), *SA 0.2s* (top right), *SA 1.0s* (bottom left) and *SA 2.0s* (bottom right).  
767 The corresponding best-fitting exponential models are denoted by solid line and dashed line for  
768 REC and ANN2BB, respectively. Moreover, for the short period response spectral ordinates (see  
769 top panel), the semivariograms (filled squares) and the corresponding best-fitting model (solid  
770 line) from HYB results are also shown for comparison.

771 **Figure 10.** Spatial correlation models,  $\rho(h)$ , obtained from the REC and ANN2BB values obtained  
772 at the accelerometric stations (solid lines) for *PGA* (left) and *SA 1.0s* (right). The dash and dash  
773 dot lines show the correlation models computed using a larger number of ANN2BB receivers  
774 located in the Northern (N) and Southern (S) side with respect to the fault at  $R_{line} < 1$

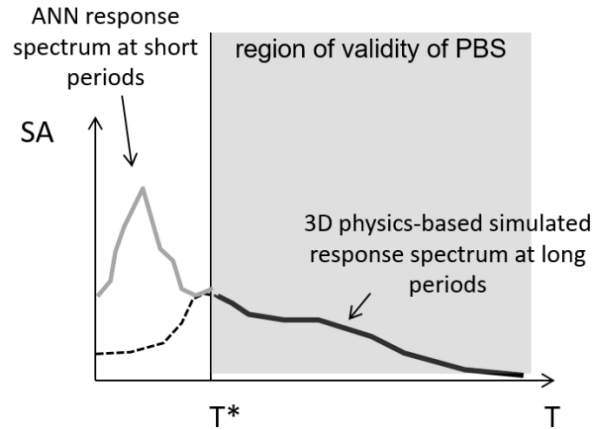

776 **Table 1.** Selection of BB earthquake ground motion simulation case studies relying on hybrid  
777 approaches\*.

Publications	$f_c$ [Hz]	Methods (LF + HF)	Area under study	Validation

778 \* Low-frequency (LF) methods: FD = Finite Difference; FE = Finite Element, SE = Spectral Element. High-  
779 frequency (HF) methods: SFF = stochastic finite-fault (Boore, 2003; Motazedian and Atkinson, 2005; Graves and  
780 Pitarka, 2010); EGF = Empirical Green's functions (Hartzell, 1978); Sc-GF = scattering Green's functions (Mai *et al.*  
781 *et al.*, 2010); St-GF = stochastic Green's functions (Kamae *et al.*, 1998).  $f_c$  denotes the cross-over frequency where low  
782 frequency (from PBS) and high frequency (stochastic) synthetics are combined.

 833 The corresponding best-fitting exponential models are denoted by solid line and dashed line for  
 834 REC and ANN2BB, respectively. Moreover, for the short period response spectral ordinates (see  
 835 top panel), the semivariograms (filled squares) and the corresponding best-fitting model (solid  
 836 line) from HYB results are also shown for comparison.

837

838 **Figure 10.** Spatial correlation models,  $\rho(h)$ , obtained from the REC and ANN2BB values obtained  
 839 at the accelerometric stations (solid lines). The dash and dash dot lines show the correlation models  
 840 computed using a larger number of ANN2BB receivers located in the Northern (N) and Southern  
 841 (S) side with respect to the fault at  $R_{line} < 1$
