HAL is a multi-disciplinary open access archive for the deposit and dissemination of scientific research documents, whether they are published or not. The documents may come from teaching and research institutions in France or abroad, or from public or private research centers. L'archive ouverte pluridisciplinaire **HAL**, est destinée au dépôt et à la diffusion de documents scientifiques de niveau recherche, publiés ou non, émanant des établissements d'enseignement et de recherche français ou étrangers, des laboratoires publics ou privés.

Simultaneous Seismic Sources Separation Based on Matrioshka Orthogonal Matching Pursuit, Application in Oil and Gas Exploration

Ekaterina Shipilova, Michel Barret[®], Matthieu Bloch[®], Jean-Luc Boelle, and Jean-Luc Collette

Abstract-We present Matrioshka orthogonal matching pur-1 suit (OMP), a method consisting of two nested OMPs for sepa-2 rating seismic sources at an early stage of the signal processing з chain. Matrioshka OMP is based on models of sensor signals 4 that place nonrestrictive assumptions on the seismic survey using 5 simultaneous sources. Our seismic event model is based on the spatial coherence of signals, which results in a straight or slightly 7 curved feature in the trace representation of the data with a 8 specific wavelet, whose magnitude can linearly vary according to 9 the offset. We demonstrate the effectiveness of the approach on 10 synthetic and real data. 11

I. INTRODUCTION

15 A. Simultaneous-Source Seismic Acquisition

14

C EISMIC surveys are performed at all stages of oil and 16 S gas exploration and development, with the objective of 17 constructing an image of the subsurface without actually 18 penetrating into the Earth's crust. To obtain such an image, 19 seismic sources generate a wavefield at or close to the sur-20 face, which then propagates into the subsurface where it is 21 altered and reflected by the geological layers and bodies. 22 The geological medium only absorbs some of the emitted 23 energy and the remaining energy escapes and reaches the 24 surface, where seismic receivers sensitive to minute vibrations 25 record it. With some assumptions regarding the propagation 26 velocities, the knowledge of the emission and detection time 27 instants, as well as the spatial positions of the sources and 28 receivers, provides information about the subsurface geometry 29 and physical properties. 30

When simultaneous sources emit their signals, or when a single source emits a long signal or makes small pauses

between subsequent short shots, one must be able to separate 33 the different sources and the different shots to identify the 34 exact time of emission associated with each seismic event 35 encountered. Since the crosstalk (effect of pollution of one 36 signal by another) between shots significantly complicates the 37 signal processing and eventually degrades image quality [1], 38 conventional seismic surveys ensure that the time and location 39 intervals between shots are large enough to avoid crosstalk. 40 Nevertheless, simultaneous-source seismic data acquisition has 41 recently attracted attention for its potential to acquire larger 42 amounts of data in a reduced time [2], which might be 43 beneficial in harsh meteorological environments [3] or because 44 of environmental regulations. 45

The idea of allowing multiple seismic sources to fire simul-46 taneously was first introduced in the seventies for marine 47 and land seismic [4], [5], but the first simultaneous shooting 48 was only implemented for land vibroseis acquisition in the 49 late nineties [6] by controlling the pattern of the sources, 50 also known as source sweeping. Since then, vibratory seis-51 mic source techniques have constantly improved, and sweep 52 generation and management is still actively ongoing [7]–[9]. 53 The first proposal of simultaneous shooting without constraints 54 on the source pattern, i.e., without specific encoding or sweep 55 management, dates back to the late nineties [10], but actual 56 implementation of appropriate logistics, survey design, and 57 processing has taken nearly a decade. The difficulty may be 58 attributed in part to the dithering of shooting times required 59 for best wavefield separation, which could result in complex 60 real-time communication and synchronization of the sources 61 in the field [11]. It was not until 2006 that BP proposed a new 62 approach called independent simultaneous sourcing (ISS^1) , 63 in which no effort is made to synchronize the sources [12], and 64 the burden is placed on the receiver to process a continuous 65 recording. Subsequent published tests on synthetic and real 66 data [13] have established the usefulness and potential of 67 data acquired in simultaneous-source mode [14]; however, 68 these early tests did not exploit any specific processing and 69 only relied on the noise attenuation capacity of stacking 70 for crosstalk suppression. Moreover, subsequent full scale 71 surveys were only held at the exploration stage, in zones 72 where structural interpretation was needed [15]–[18]. To speed 73 up seismic campaigns, industry is now envisioning the use 74 of simultaneous shooting at all exploration and development 75 stages, including those having reservoir characterization [19], 76

¹ISS is a registered trade mark of BP p.l.c.

[20] and monitoring [21]–[24] purposes. Consequently, more sophisticated processing is needed to achieve the high precision necessary at these stages. Seismic processing engineers could also benefit from simultaneous sources separation
methods to suppress interference between neighboring seismic
surveys [25].

The seismic data resulting from simultaneous-source shoot-83 ing is now colloquially known as blended data. The methods 84 proposed to process blended seismic data can be classified into 85 the three following groups. Most of them impose constraints 86 on data acquisition, as the firing times of different sources 87 must be random enough, except for some completely differ-88 ent techniques, such as seismic apparition [26] or coherent 89 simultaneous shooting [27]. 90

Random Noise Attenuation: These methods consist in presenting the signal coming from each source as being coherent and removing the incoherent signals coming from the other sources using conventional denoising procedures such as median filtering [28]–[30], prediction error filtering [31], or a combination of these filters [32].

2) Inversion-Based Source Separation: These methods 97 treat the signals of each source as signal and not as noise; 98 they aim to explain all interpretable signals present in 99 the data. The inversion approach has been the most 100 successful so far and has been shown to render superior 101 performance over the random noise attenuation [33]. 102 The common mathematical formulation of such methods 103 is given in [34]; this includes a coherency constraint 104 usually expressed in a transform domain rather than the 105 (t, x) domain, e.g., Fourier domain [35]–[37], Radon 106 domain [38], curvelet domain [39], seislet domain [40], 107 or in more sophisticated domain combinations [41]-108 [43]. The method presented in this article falls into this 109 category. 110

3) *Direct Imaging of Blended Data:* These methods aim at processing blended data without explicit separation [44].
This approach has the potential to reduce computational complexity, since explicit source separation typically increases the amount of data volumes to process: a separate data set is created for each source.

¹¹⁷ Direct imaging methods might be the most promising in the ¹¹⁸ future but would require a complete and costly overhaul of the ¹¹⁹ currently used seismic signal processing chain. Since existing ¹²⁰ state-of-the-art industrial seismic processing algorithms are not ¹²¹ compatible with blended data, there is still much interest in ¹²² deblending the raw seismic signals to keep the subsequent ¹²³ processing unchanged.

Many of the currently proposed deblending methods need 124 some preprocessing of the data, e.g., surface wave suppres-125 sion [33]. In this article, we propose to use a data-driven 126 seismic event model in a greedy decomposition to obtain a sep-127 aration suitable for application at the earliest processing stages. 128 We start by briefly recalling in Section II notions of seismics 129 from a perspective that facilitates the description of our method 130 and identifies the conditions required for our method to apply. 131 We then introduce in Section II-C the data-driven parametric 132 model of a seismic event, which includes a curvature parameter 133 and a magnitude attenuation factor depending on the position 134

of the source. We describe in Section III the main contributions of this article, which are the data-driven model and the decomposition method implementation. We also state in Sections II and III the assumptions that are necessary and sufficient to apply our method. Finally, we illustrate in Section IV the performance of our method on synthetic and real seismic data.

B. Signal Decomposition and Orthogonal Matching Pursuit 141

Let the signal to decompose be $d(t) \in \mathcal{H}$, where \mathcal{H} is 142 a Hilbert space, with inner product and Euclidean norm, 143 respectively, defined by $\langle d, g \rangle = \int_{-\infty}^{+\infty} d(t)\overline{g}(t) dt$ (where \overline{g} is 144 the complex conjugate of g) and $||d|| = \langle d, d \rangle^{1/2}$. The inner 145 product becomes $\langle d, g \rangle = \sum_{t \in \Delta_t \mathbb{Z}} d(t) \overline{g(t)}$ after sampling 146 with a period Δ_t . A *dictionary* \mathcal{D} is a subset $\{g_{\gamma}(t)\}_{\gamma \in \Omega} \subset \mathcal{H}$ 147 comprised of unit-norm vectors indexed by a set $\Omega \subset \mathbb{R}^{\nu}$, 148 with $\nu \in \mathbb{N}$. The elements of a dictionary are called *atoms*. 149

When decomposing a signal d into a linear combination of 150 L D-atoms, we look for a subset $\Gamma \subset \Omega$ of L elements and 151 complex numbers $\{c_{\gamma}\}_{\gamma \in \Gamma}$ that lead to the smallest approx-152 imation error $\min_{\{\Gamma \subset \Omega: |\Gamma| = L\}} \min_{\{c_{\gamma}\}} \|d - \sum_{\gamma \in \Gamma} c_{\gamma} g_{\gamma}\|$. If 153 we knew L and Γ a priori, we could solve this problem with 154 least-squares methods. However, for such complex dictionaries 155 as ours, we cannot fix L and Γ beforehand; we first have 156 to choose an optimal set of atoms and then find a linear 157 combination that best approximates the signal. 158

Greedy algorithms, such as matching pursuit (MP) [45] and 159 orthogonal matching pursuit (OMP) [46], provide an efficient 160 solution to that problem. It consists in constructing successive 161 approximations of d by making orthogonal projections on ele-162 ments of \mathcal{D} . Let us set $R^0 d = d$ and suppose that the $(\ell - 1)$ th 163 order residue $R^{\ell-1}d$ is computed for $\ell \geq 1$. Then, $R^{\ell-1}d$ 164 is decomposed into $R^{\ell-1}d = \langle R^{\ell-1}d, g_{\gamma_{\ell}} \rangle g_{\gamma_{\ell}} + R^{\ell}d$. This leads to $\langle R^{\ell-1}d, g_{\gamma_{\ell}} \rangle = \langle R^{\ell-1}d, g_{\gamma_{\ell}} \rangle \langle g_{\gamma_{\ell}}, g_{\gamma_{\ell}} \rangle + \langle R^{\ell}d, g_{\gamma_{\ell}} \rangle$, which shows that the residue $R^{\ell}d$ is orthogonal to $g_{\gamma_{\ell}}$, 165 166 167 since the atoms are unit-norm vectors. Hence, $||R^{\ell-1}d||^2 =$ 168 $|\langle R^{\ell-1}d, g_{\gamma_{\ell}}\rangle|^2 + ||R^{\ell}d||^2$, and to minimize the norm of the 169 residue $||R^{\ell}d||$, one must choose $g_{\gamma_{\ell}} \in \mathcal{D}$ such that 170

$$\langle R^{\ell-1}d, g_{\gamma_{\ell}} \rangle| = \max_{\gamma \in \Omega} |\langle R^{\ell-1}d, g_{\gamma} \rangle|. \tag{1}$$

If we now carry the decomposition up to the Lth order, 172 we obtain: $d = \sum_{\ell=1}^{L} \langle R^{\ell-1}d, g_{\gamma_{\ell}} \rangle g_{\gamma_{\ell}} + R^{L}d$ and $||d||^{2} = \sum_{\ell=1}^{L} |\langle R^{\ell-1}d, g_{\gamma_{\ell}} \rangle|^{2} + ||R^{L}d||^{2}$, which proves that the residue 173 174 norm is decreasing. At this stage, the signal d is modeled 175 as a finite linear combination of L atoms with an error 176 $R^{L}d$. However, this model can be improved using the same 177 dictionary, since $R^L d$ is generally not orthogonal to V_L , 178 the linear span of $\{g_{\gamma_\ell}\}_{1 \le \ell \le L}$: it is only orthogonal to the 179 last selected atom $g_{\gamma L}$. The OMP algorithm corrects this 180 shortcoming by computing orthogonal projections at each 181 iteration. As in MP, at iteration ℓ the algorithm selects an 182 atom $g_{\nu_{\ell}}$ solving (1), builds an orthogonal basis of V_L using 183 the Gram-Schmidt orthogonalization, and uses it to compute 184 the orthogonal projection of d on V_L . With OMP, the residue 185 norm is also proven to decrease monotonically. 186

Greedy algorithms have already been applied to seismic data 187 for several different purposes, such as filtering [47], linear 188

noise suppression [48], [49], seismic data interpolation and
regularization [50], [51], seismic data compression and sparse
storage [52], [53], or reflectivity inversion [54], but few, if any,
contributions have considered their application to the problem
of separating signals from different sources.

II. MODELING SENSOR SIGNALS IN SIMULTANEOUS SOURCES SEISMIC SURVEY

We introduce our model of simultaneous-source seismic surveying and highlight the assumptions that justify our datadriven model for simple geometries of the Earth's subsurface.

199 A. Earth's Transfer Function

We consider an ocean bottom seismic acquisition with 200 $K \geq 1$ sources $\{S_k\}_{1 \leq k \leq K}$ and a single sensor D located at 201 fixed positions in the Earth's space-time referential. We denote 202 the kth source excitation by $s_k(t)$, and the measured signal 203 by d(t), both time-dependent. The Earth acts as a filter 204 (i.e., a linear, time-shift invariant, and continuous system) for 205 the emitted signals $s_k(t)$, which enables us to represent the 206 recorded signal as a convolution product $d(t) = \sum_{k=1}^{K} (r_k \star$ 207 $s_k(t)$, with the Earth's response coefficients r_k depending on 208 the positions of all the sources and the detector. Each source S_k 209 makes N_k shots at times $\{T_n^k\}_{n \in [[1; N_k]]}$ and in the corresponding 210 positions $\{\mathbf{x}_n^k\}_{n \in [\![1]; N_k]\!]}$. We also make the following hypothesis. 211 Hypothesis 1: Source S_k emits the same short excitation s_k 212 for each of its shots. 213

²¹⁴ Consequently, the signal d(t) is given by

²¹⁵
$$d(\mathbf{x}_{D}, t) = \sum_{k=1}^{K} \sum_{n=1}^{N_{k}} \left(r_{k} \left(\mathbf{x}_{n}^{k}, \mathbf{x}_{D} \right) \star s_{k} \right) \left(t - T_{n}^{k} \right) + b(t) \quad (2)$$

where b(t) is the additive noise capturing the unavoidable 216 imperfections of real seismic acquisitions. Note that $r_k(\mathbf{x}_n^k, \mathbf{x}_D)$ 217 from (2) does not correspond to the true Earth reflectivity 218 between \mathbf{x}_n^k and \mathbf{x}_D (the detector position) but acts as a 219 transfer function between the source and receiver locations 220 that accumulates Earth's entire response. Since the posi-221 tion of the detector is constant, we will write d(t) instead 222 of $d(\mathbf{x}_D, t)$. 223

224 B. Simultaneous Sources for Classical Seismic Survey Design

Experimental Conditions for Simultaneous-Source Surveys: We assume that each receiver continuously records all
 the seismic signals produced during the acquisition, which

requires that all the survey equipment be kept synchronized. 228 Time ranges from 0 to T_{glob} , the global acquisition time. 229 We make the following hypothesis. 230

Hypothesis 2: The sources fire along straight lines, which may differ for different sources.

As illustrated in Fig. 1, the moveout of each seismic event depends on the source location along its shooting line. After sampling with period Δ_t , the recorded data have the shape of a column matrix $d(k) = d(k\Delta_t)$. This type of recording is specific to simultaneous sources surveys. We further make two realistic hypotheses to simplify our analysis. 238

Hypothesis 3: Each source makes pauses between consecutive shots, during which its emitted signal is null.

Hypothesis 4: Shooting times of different sources are asyn-241 chronous and shooting intervals of each source are random. 242 The benefit of Hypotheses 3 and 4 is illustrated in Fig. 2, 243 in which we align the data according to the shooting times of 244 different sources. Each shot of the same source can be distin-245 guished from the others following the time axis and the shots 246 of different sources can be separated using a spatial coherence 247 criterion-as detailed in Section II-C-which consists in a 248 straight or slightly curved feature in the representation space 249 (t, x) of the data. 250

2) (t, x) Representation Spaces of the Data : We define a 251 linear operator, called pseudo-deblending, to align the sensor 252 signal by the source *i* to form the traces (see Fig. 3). For d(t)253 from (2), it is written as $\mathcal{A}_i : L^2(\mathbb{R}) \to L^2([0, \max_n(T_{n+1}^i -$ 254 $T_n^i) > [x_{\min}^i, x_{\max}^i]), \ d(t) \mapsto \mathbf{D}_i(t', x) = d(t' + T_n^i), \ \text{if } x = x_n^i - x_0^i \ \text{and} \ t' \in [0; \ T_{n+1}^i - T_n^i]; \ \mathbf{D}_i(t', x) = 0, \ \text{otherwise.}$ 255 256 Pseudo-deblending creates as many data representation spaces 257 (t, x) as there are sources. To simplify, the (t, x) representation 258 space is called in the following a (t, x) trace domain. 259

In conventional single source seismic, the operation A_i 260 is done implicitly: the data are cut into traces according to 261 the shooting times T_n^i , which do not play any further role 262 in the processing. In contrast, for *simultaneous-source* data 263 processing, it is crucial to preserve the shooting times, as they 264 contain critical information to separate the signals coming 266 from different sources. 266

We introduce these notions to clarify the concept of a *seismic event*, used in our data-driven model and related to the notion of traveltime curve, the graph of the time that a seismic wave spends to travel from the shot point to the receiver point. Note that the knowledge of the firing times and positions of each source makes it easy to switch from a 1-D representation to any 2-D trace domain representation of 270

231

232

239

Fig. 2. Separation by random shot-times. Data aligned according to the (Left) first and (Right) second source shot-times. Dark (resp. light) wiggles correspond to the aligned (resp. nonaligned) source.

Fig. 3. Example of (t, x) representations of a continuous signal cut into traces with regular shooting times T_n^1 for the first source and irregular ones T_n^2 and T_n^3 for the second and the third sources, respectively. Zero padding (the white squares correspond to zeros) is applied in order to keep the matrices rectangular.

the signals and vice versa. Therefore, with a slight abuse of
language, we use the same terminology for events and patterns
in 1-D and 2-D representations, even though such events or
patterns are only clearly visible in 2-D representations.

Hypothesis 5: Traveltime curves of coherent seismic waves
(e.g., direct waves, surface waves, and reflected waves) are
identifiable in one (and only one) seismic traces domain.

Traveltime curves are usually close to straight lines, parabolas, or hyperbolas in synthetic and real seismic data [55]. This observation and Hypothesis 5 imply the possibility of decomposing d(t) into a sum of a finite number of coherent features that have a reasonably simple mathematical representation, as we shall see in Section II-C.

287 C. Data-Driven Seismic Event Model

We now introduce our parametric model of a seismic event that may either carry information about the Earth's subsurface geometry or correspond to a direct arrival. This model, which includes a curvature parameter, a magnitude attenuation factor depending on the source positions and the wavelet's decomposition into a sum of simple signals, and its implementation are the main contributions of this article.

1) Decomposition Into a Sum of Seismic Events: Actual
 seismic data usually have a significant size: one gather can

contain hundreds of traces acquired with maximal offsets 297 of 6 km or more. In complex geological environments with 298 lateral velocity and density variability, it is difficult to establish 299 a data-driven seismic model that would directly apply to the 300 whole gather. Therefore, we choose to restrict our area of 301 search to N seismic traces in the (t, x) domain, with N 302 typically between 10 and 30 depending on the data complexity. 303 This allows us to make the following reasonable hypothesis. 304

Hypothesis 6: The wavelet w(t) found in the data does not vary significantly from one seismic trace to another within some constrained spatial window of N seismic traces.

When dealing with multiple sources recorded by the same 308 receiver, which results in multiple (t, x) trace domains to 309 consider, one must adopt a consistent decomposition strategy. 310 There may be several relevant ones, such as fully explaining 311 all coherent features in the first source before passing on to 312 the second one. If we were to follow this strategy, we would be 313 able to cut our data into traces once, using the A_i operator for 314 each source i, and continue with the 2-D (t, x) trace domain 315 representation common for a geophysicist. This approach has 316 the following disadvantage: the algorithm aims at retrieving 317 the low-amplitude signal hidden by the high-amplitude blend-318 ing noise originating from the other sources. We propose to 319 simultaneously work in all the (t, x) trace domains in order to 320 first identify and subtract the globally most energetic features 321 and then continue with less energetic ones. The less energetic 322 features are initially hidden under the crosstalk but are revealed 323 by the first iterations of the algorithm. This is the main 324 reason why we stick to the 1-D representation of the data. 325 The decomposition is therefore simultaneously performed in 326 all the sources (t, x) trace domains, in which we look for 327 particular identifiable features that we call seismic events. 328 To do so, we first have to find in the column matrix $d(k\Delta t)$ 329 the N-traces part of the signal corresponding to each of the 330 sources. We then represent the data d(t) as a finite sum of 331 seismic events $h_{\ell} \star w_{\ell}(t)$ 332

$$d(t) = \sum_{\ell=1}^{L} h_{\ell} \star w_{\ell}(t) + R^{L} d(t).$$
 (3) 333

Our model consists of two parts: h(t), called *traveltime curve* ³³⁴ (we call it curve because of the trace representation (t, x) ³³⁵ of 1-D signals), contains all the parameters related to the wave ³³⁶

propagation time (medium characteristics), distance between 337 the sources and the receiver, the sources firing times and the 338 linear amplitude variation from one trace to another; w(t), 339 called signature or wavelet, is associated with the excitations 340 emitted by the sources and distorted by propagation and 341 reflection. Note that even if (2) and (3) are similar, there 342 is a significant difference between the reflectivity $r_i(\mathbf{x}_n^i, \mathbf{x}_D)$, 343 which is Earth's transfer function between the locations of the 344 detector and of the nth shot of source i, and the traveltime 345 curve h(t), which indicates the position of a seismic event 346 in the traces domain and is driven by the data. Moreover, 347 the residue $R^{L}d(t)$ generally differs from the noise b(t). In 348 the case of two sources, we rewrite (3) as 349

$$_{350} \quad d(t) = \sum_{\ell=1}^{K_1} h_{\ell}^{(1)} \star w_{\ell}^{(1)}(t) + \sum_{\ell=1}^{K_2} h_{\ell}^{(2)} \star w_{\ell}^{(2)}(t) + R^L d(t) \quad (4)$$

with $K_1 + K_2 = L$ and where the first (resp. second) sum 351 corresponds to the seismic events identifiable in the (t, x)352 traces domain of the first (resp. second) source. Thus, a perfect 353 deblending would consist in reducing the residue $R^{L}d(t)$ to 354 the ambient noise, as in this case, each sum would correspond 355 to the isolated signal of the corresponding source. Before 356 developing this point in Section III, we clarify the concepts of 357 traveltime curve and wavelet in Sections II-C2 and II-C3. 358

2) Traveltime Curve Model: If we omit the amplitude vari-359 ation, a traveltime curve is a graph of arrival time depending 360 on the coordinates of the detector and the source shots. One 361 can prove [55] that, for a simple case of a single horizontal 362 reflector with a constant velocity above it, the traveltime curve 363 is a hyperbola. Furthermore, with reasonable accuracy, one can 364 model the arrival time function of a coherent seismic wave as a 365 straight or slightly curved line in the (t, x) trace domain within 366 some lateral processing window (the closer the shot is to the 367 receiver, the more curvature is observed). This assumption 368 holds if the acoustic and elastic properties of the subsurface 369 do not abruptly change in the horizontal direction within the 370 chosen lateral processing window. The "pure" traveltime part 371 $\tilde{h}(t)$ of the seismic event takes the form 372

373
$$\tilde{h}^{(i)}(x_n^i, t) = \delta\left(t - \tau - p(x_n^i - x_0^i) - q\left(\frac{x_n^i - x_0^i}{x_{\max}^i - x_{\min}^i}\right)^2\right)$$
 (5)

or, for the convenience of our computation, in 1-D

375
$$\tilde{h}^{(i)}(t) = \sum_{n=1}^{N} \delta \left(t - \tau - p \left(x_n^i - x_0^i \right) - q \left(\frac{x_n^i - x_0^i}{x_{\max}^i - x_{\min}^i} \right)^2 - T_n^i \right).$$

376 (6)

Equations (5) and (6) are equivalent, but we stick to the 377 1-D representation to highlight the specific nature of the 378 simultaneous-source data. Note that we omit the index ℓ 379 present in (3) to alleviate notation. Here, *i* is the index of 380 the source associated with the event; N the number of shots 381 taken into account to construct the event; x_0^i , x_{\min}^i and x_{\max}^i are 382 the reference coordinates of the *i*th source; $\delta(t)$ is the Dirac 383 distribution; τ , p, and q are the parameters that define the 384 seismic event: the reference time, the slope and the curvature. 385

Finally, to obtain the full traveltime curve, we add a linear 386 amplitude variation parameter α to this representation and 387 obtain 388

$$h^{(i)}(t) = \sum_{n=1}^{N} \left[1 + \alpha \left(x_n^i - x_0^i \right) \right]$$
389

$$\times \delta \left(t - \tau - p \left(x_n^i - x_0^i \right) - q \left(\frac{x_n^i - x_0^i}{x_{\max}^i - x_{\min}^i} \right)^2 - T_n^i \right).$$
(7) 390

Note that the attenuation factor $1 + \alpha (x_n^i - x_0^i)$ cannot van-391 ish when $x_n^i = x_0^i$ in (7). We shall see in the following 392 (Section III-B and criterion (13)) how one can address such 393 a case. Strictly speaking, (7) defines an amplitude-variation-394 preserving traveltime curve, but for brevity we use the term 395 traveltime curve in the following. It is worth noting that differ-396 ent sources illuminating the same area in the subsurface, e.g., 397 an interface between two geological layers approximately at 398 the same location, correspond to a single *physical* (geological) 399 event; however, with our model (4), we obtain at least one 400 separate seismic event per source. Moreover, even though our 401 seismic event atoms correspond to simple cases of physical 402 events, their linear combinations allow us to model complex 403 physical situations (see Section IV). 404

3) Wavelet Model: Wavelet estimation has been a long-405 standing issue in seismic prospecting and different methods 406 have been suggested in the literature. We focus on methods 407 based on coherence; in other words, from Hypothesis 6, 408 we assume that the wavelet does not abruptly change from 409 trace to trace in a seismic event. This is intuitively justified by 410 Hypothesis 1, and the fact that Earth's response to excitations 411 varies slowly with respect to the source displacement. Never-412 theless, we take into account the eventual presence of low and 413 high energy noise that may perturb the wavelet originating 414 from a single source by averaging the wavelet encountered 415 in neighboring traces after getting rid of eventual outliers. 416 Since propagation and reflection distort the source signals, 417 the wavelet encountered in seismic gathers differs from the 418 signal emitted by the source, and we suppose that the wavelet 419 differs from one seismic event to another, even if it originates 420 from the same seismic source. 421

As already mentioned, a single physical event may be 422 captured by a sum of several seismic events, so we look for 423 a new seismic event within a limited time interval that we 424 denote $[-M\Delta_t, M\Delta_t]$ and call "corridor" (M is an integer 425 meta-parameter). This corridor is defined along a traveltime 426 curve of the form (7), which is assumed known for now. 427 It must be large enough not to change the wavelet spec-428 trum. The fact that the traveltime curve $h^{(i)}$ is not perfectly 429 known is addressed in Sections III-B and III-D. After get-430 ting a first estimation $\hat{w}^{(i)}$ of the wavelet $w^{(i)}$, we refine 431 the estimation thanks to optimization stages described in 432 Section III-C2. To reduce the dimension of the optimization 433 problem, we choose to decompose the estimated wavelet into 434 a linear combination of a small number of wavelet atoms. 435 We also choose wavelet atoms that can be represented analyt-436 ically, e.g., Ricker and Ormsby wavelets, which are elementary 437 wavelets widely used in seismic exploration and for which 438

Fig. 4. Power spectrum of the signal of length 500 ms in black, reconstructed using 178 Ricker (in dark gray), or 212 Ormsby (in light gray), wavelets.

we can explicitly compute temporal derivatives. This allows 439 us to reduce the computational complexity of our algorithm 440 optimization stages. 441

We choose to decompose the estimated wavelet into a linear 442 combination of a small number of wavelet atoms using the 443 OMP algorithm, which requires the identification of an adapted 444 dictionary. We shall see in Section III-C1, how we construct a 445 finite number S (of several units) of classical wavelet shapes 446 from a preliminary spectral analysis of the data. The index 447 s denotes the shape of the wavelet $w_s(t)$, and the dictionary 448 consists of atoms (before normalization) { $w_s(t-\tau)$: 1 \leq 449 $s \leq S, \tau \in [0, T]$ where T > 0 is a meta-parameter. Thus, 450 we obtain the following parametric wavelet estimation: 451

452
$$\hat{w}^{(i)}(t) = \sum_{k=1}^{K} a_k w_{s_k}(t - \tau_k) + R^K \hat{w}^{(i)}(t)$$
 and
453 $w^{(i)}(t) = \sum_{k=1}^{K} a_k w_{s_k}(t - \tau_k).$ (4)

k=1

Fig. 4 shows the power spectrum of a modeled marine 454 seismic source signature. We observe that the parametric 455 model of the form (8) is accurate enough in the useful part of 456 the spectrum both with Ricker (K = 178 for this example) and 457 Ormsby (K = 212) wavelets. Note that these numbers are sig-458 nificantly larger than those used in our deblending algorithm 459 because here the whole length of the source signal is taken 460 into account (0.5 s) with a very dense sampling (0.5 ms of)461 period). For subsequent simulations we use narrower corridors 462 for wavelet estimation, typically 0.1 s, with $\Delta_t = 2$ ms. 463

III. MATRIOSHKA OMP IMPLEMENTATION 464

We now present the implementation of our algorithm. 465 In Section III-A, we present the fundamentals of our method, 466 which we call Matrioshka OMP and which relies on detailed 467 parameter optimization. To obtain suitable parameter values, 468 we use iterative optimizations, which require a sufficiently 469 accurate prior knowledge of the parameters, i.e., satisfac-470 tory initial conditions. The initial condition computation is 471 described in Section III-B. Sections III-C and III-D provide 472 an overview of the different parts of the algorithm. 473

A. Deblending Using Data-Driven Model and OMP

An iterative method that performs a decomposition as in (4)475 automatically results in a partial deblending of the data. 476 Moreover, if the first terms in this decomposition correspond 477 to the seismic events having the most energy, then only the 478 lowest energy cross-talks are left in the residue $R^{L}d(t)$, which 479 can then be handled by classical seismic processing techniques 480 as if no other sources had been firing simultaneously. Conse-481 quently, we look for a decomposition (4) in which the most 482 energetic features of the deblended signal associated with the 483 *i*th source are found in the sum 484

$$\sum_{\ell=1}^{K_i} h_{\ell}^{(i)} \star w_{\ell}^{(i)} \tag{9} 485$$

474

and the most energetic cross-talks due to the other sources are 486 captured in the sums 487

$$\sum_{\ell=1}^{K_j} h_\ell^{(j)} \star w_\ell^{(j)} \quad \text{with } j \neq i \tag{10} \quad {}_{466}$$

to allow classical processing of the deblended data $\sum_{\ell=1}^{K_i} h_{\ell}^{(i)} \star w_{\ell}^{(i)} + R^L d(t)$. To successfully deblend with this approach, it is 489 490 crucial that the sum (9) contains the most energetic features 491 of the deblended signal associated with the source *i* and not 492 any coherent seismic events originating from a source $i \neq i$. 493 Hypotheses 2, 3, and 4 justify the fact that we can expect 494 to capture in the sum (9) seismic events originating from the 495 source *i* alone. Moreover, if the most energetic features are 496 identified at the first iterations of the decomposition, then the 497 most energetic cross-talks from other sources are captured in 498 other sums (10), and thus, do not pollute the residue $R^{L}d(t)$ 499 any more. Fortunately, this is exactly how OMP proceeds 500 provided that we choose a well-adapted dictionary. Now, if the 501 atoms are expressed, before normalization, as $\mathcal{G}_{\gamma} = h^{(i)} \star w^{(i)}$, 502 and $h^{(i)}$ and $w^{(i)}$ given, respectively, by (7) and (8), then 503

 $\mathcal{G}_{\gamma}(t)$

$$=\sum_{n=1}^{N} \left[1 + \alpha \left(x_{n}^{i} - x_{0}^{i}\right)\right] \sum_{k=1}^{K} a_{k}$$
 so

$$\times w_{s_k} \left(t - \tau - p \left(x_n^i - x_0^i \right) - q \left(\frac{x_n^i - x_0^i}{x_{\max}^i - x_{\min}^i} \right)^2 - T_n^i - \tau_k \right)$$
(11) 50

504

with $\gamma = \{i, \tau, p, q, \alpha, K, \{s_k, a_k, \tau_k\}_{1 \le k \le K}\}$ the complete 508 set of parameters. Hence, we can construct a decomposi-509 tion (4) that fulfills the aforementioned conditions required 510 for deblending. Examples of such atoms, given in Fig. 5, show 511 the ability of the algorithm to handle curvature and amplitude 512 variation. 513

Note that, when L tends to infinity, the residue $R^{L}d$ is not 514 necessarily white noise or any other type of noise. Indeed, 515 it corresponds to the last residue (part of the signal) not 516 explained by the dictionary, i.e., orthogonal to the dictionary used for decomposition. A "good" decomposition, though, 518 would leave the noise in the residue. 519

Fig. 5. Examples of atoms $\mathcal{G}_{\gamma}(t)$ (before normalization) of the seismic events dictionary.

To simplify the computation of vector norms $\|\mathcal{G}_{\gamma}\|$, we make 520 the following hypothesis. 521

Hypothesis 7: For each source, the pauses between two 522 consecutive shots are significantly longer than the emission 523 time of each shot of the same source. 524

Note that Hypothesis 7 does not forbid crosstalk between 525 consecutive shots of the same source, i.e., the delay between 526 consecutive shots can be smaller than the listening time 527 implying auto-pollution or self-simultaneous sourcing. 528

Now, the problem is to find an approximate solution of (1). 529 For this, we must overcome two major difficulties: 1) the 530 objective function to maximize is not concave and 2) the 531 number of parameters describing an atom is too large for 532 sampling the dictionary into a finite subset of atoms $\Gamma \subset \Omega$. 533 To overcome the first difficulty, we use iterative optimization 534 algorithms that converge to a local maximum whose position 535 depends on the initial conditions. It is therefore crucial to accu-536 rately choose the initial conditions. To overcome the second 537 difficulty, we gradually build atoms of the dictionary close to 538 the desired maximum. 539

B. Initial Conditions of the OMP Optimization Step

С

In this section, we present our approach to find the initial conditions of the iterative algorithm. We construct an atom \mathcal{G}_{ν} (before normalization) given by (11) in several steps. We start by building the traveltime curve $h^{(i)}$ given in (7), first looking for parameters i, τ, p, q that maximize the objective function

$$(i, \tau, p, q) = \left| \sum_{n=1}^{N} R^{\ell-1} d\left(\tau + p\left(x_n^i - x_0^i\right) + q\left(\frac{x_n^i - x_0^i}{x_{\max}^i - x_{\min}^i}\right)^2 + T_n^i \right) \right|.$$

$$(12) \qquad (12) \qquad (13) \qquad (13$$

In other words, noting that $C(i, \tau, p, q) = |\tilde{h}^{(i)} \star \widetilde{R^{\ell-1}d}(0)|$, 549 for $\tilde{h}^{(i)}$ introduced in (6), and $\widetilde{R^{\ell-1}d}(t) = R^{\ell-1}d(-t)$, we are 550 looking for a traveltime curve $\tilde{h}^{(i)}$ that maximizes the magni-551 tude of its correlation at time t = 0 with the residue $R^{\ell-1}d(t)$ 552 at the ℓ th OMP iteration. Here too, the objective function is not 553 concave, and the parameters i, τ, p, q that maximize (12) are 554 found using an iterative optimization algorithm starting from 555 suitable initial conditions and converging to a local maximum. 556 To do so, we introduce the following hypothesis. 557

Hypothesis 8: To maximize the objective function in (12), 558 good initial conditions are q = 0 and the values of i, τ, p that 559 maximize the slant stack magnitude of the residue $R^{\ell-1}d$.

Various successful applications of slant stack (or Linear 561 Radon Transform) to seismic data processing justify this 562 hypothesis, for example, coherent noise suppression, such 563 as multiples and direct arrivals removal [56]; plane-wave 564 decomposition for velocity picking [57]. In our case, if one 565 can pick the absolute maximum in the (τ, p) domain, this 566 maximum identifies a real seismic event with nearly the most 567 energy. Once we have identified a traveltime curve $h^{(i)}$ that 568 maximizes its correlation with the residue, we compute the 569 coefficients α' and β' of the linear regression between the term 570 $R^{\ell-1}d(\tau + p(x_n^i - x_0^i) + \cdots)$ appearing in (12) and $x_n^i - x_0^i$ 571 for $1 \le n \le N$ that minimize 572

$$C(\alpha',\beta') = \sum_{n=1}^{N} \left[R^{\ell-1} d\left(\tau + p\left(x_n^i - x_0^i\right) + q\left(\frac{x_n^i - x_0^i}{x_{\max}^i - x_{\min}^i}\right)^2 + T_n^i\right) \right] \right]^{574}$$

$$-[\beta' + \alpha' (x_n^i - x_0^i)] \bigg]^2$$
(13) 575

in order to obtain a first estimation of the complete traveltime 576 curve $h^{(i)}$ given in (7). In addition, when $|\beta'| > \varepsilon$ (in our 577 implementation we took $\varepsilon = 10^{-7}$), we set $\alpha = \alpha'/\beta'$. 578

We observed that criterion (12) does not give the best 579 initial conditions to the OMP optimization when the factor 580 $\beta' + \alpha'(x_n^i - x_0^i)$ changes its sign between the extreme values 581 of x_n^i and we shall see in Section III-E how to modify (12) to 582 obtain better initial conditions. 583

Next, we define a "corridor" in the representation space 584 (t, x) associated with the *i*th source. This corridor has a width 585 of $(2M+1)\Delta_t$, it is centered around the maximal values of $h^{(i)}$ 586 and passes through the N considered traces. We thus obtain a 587

540

541

542

543

544

545

⁵⁸⁸ nonparametric estimation $\hat{w}^{(i)}$ of the wavelet $w^{(i)}$, associated ⁵⁸⁹ with the atom \mathcal{G}_{γ} introduced in (11). The estimation is locally ⁵⁹⁰ made from the current residue, within the corridor and after ⁵⁹¹ making the following hypothesis.

Hypothesis 9: A wavelet estimation can be statistically
 derived from the N traces by stacking along curves parallel to
 the traveltime curve maxima weighted by attenuation factors.

We then apply a Tukey window to this nonparametric wavelet estimation to avoid discontinuities at the corridor edges. Finally, we obtain a parametric estimation $w^{(i)}$ of the wavelet having the form (8) by applying the OMP algorithm to the windowed wavelet estimation, and we compute the nonnormalized atom \mathcal{G}_{γ} , mentioned at the beginning of this section, as $h^{(i)} \star w^{(i)}$.

We can summarize the computation of the initial conditions \mathcal{G}_{γ} into the following stages.²

- 1) Find the values $i, \hat{\tau}$, and \hat{p} that maximize the slant stack magnitude of the residue $R^{\ell-1}d$.
- ⁶⁰⁶ 2) From the initial conditions obtained at the previous stage and q = 0, find a traveltime curve $\tilde{h}^{(i)}$ maximizing its correlation magnitude with $R^{\ell-1}d$ at time t = 0, within the *N* traces.
- ⁶¹⁰ 3) Find the coefficients α' and β' of the regression (13) to ⁶¹¹ obtain $\alpha = \alpha'/\beta'$ and the amplitude-variation-preserving ⁶¹² traveltime curve $h^{(i)}(t)$, with the attenuation factor ⁶¹³ $1 + \alpha(x_n^i - x_0^i)$.
- 4) In the (t, x) trace domain associated with source *i*, identify a $(2M+1)\Delta_t$ -seconds high corridor centered around the traveltime curve maxima found at the previous stage; then make a nonparametric wavelet estimation using a weighted stacking by reverse attenuation factors along the curves parallel to the $\tilde{h}^{(i)}$ maxima within the corridor.
- 5) Window the nonparametric wavelet estimation obtained at the previous stage and apply OMP to get a parametric estimation $w^{(i)}$ given by (8).
- 623 6) Find the initial conditions atom which, before normalization, equals to $\mathcal{G}_{\gamma} = h^{(i)} \star w^{(i)}$.

In this way, we propose to perform deblending by means of OMP, and we use the OMP algorithm twice. To distinguish them, we denote by *outer* OMP, the one which has a dictionary of atoms of the form (11) before normalization, and by *inner* OMP, the one performing the parametric wavelet estimation. In Section III-C, we present the *inner* OMP algorithm.

631 C. Inner OMP Overview

Before starting the iterations of Matrioshka OMP, we per-632 form a spectral analysis of the data to determine the shapes 633 of the wavelets to use in the inner OMP dictionary. For this, 634 we compute the power spectrum of d(t) and pick the frequency 635 values at its maximum and 3 and 6 dB lower. This procedure 636 provides a set of frequencies that we use to build the wavelet 637 dictionary (for example, the five frequencies above give the 638 dominant frequencies of the Ricker wavelets). 639

1) Wavelet Dictionary: We choose a finite number S of 640 classical wavelet shapes. The shape index s $(1 \le s \le S)$ 641 corresponds to either a Ricker wavelet with a given dominant 642 frequency or an Ormsby wavelet with a given set of cut-off 643 frequencies. If we need Ricker wavelets of different dominant 644 frequencies, we use as many Ricker shapes as needed and 645 likewise for Ormsby wavelets. The predefined shapes can be 646 extended to any other kind of wavelets. 647

The dictionary is composed of time-shifted unit-norm ele-648 mentary wavelets of the predefined shapes. Since the estimated 649 wavelet must be inside the abovementioned corridor, we limit 650 the time shifts so that an atom is represented as $w_{\nu}(t) =$ 651 $(w_s(t - \nu \Delta'_{\tau} - \tau'))/||w_s(t)||$, where $\nu \in [[-\mu M, \mu M]]$ is 652 an integer, $\tau' \in](-\Delta'_{\tau}/2), \Delta'_{\tau}/2[$ with $\Delta'_{\tau} = \Delta_t/\mu$, and 653 $\mu^{-1} \in \mathbb{N}$ divides M. Thus, the dictionary is $\mathcal{D} = \{w_{\gamma}\}_{\gamma \in \Omega}$ 654 with $\Omega = \{(s, v, \tau'): s \in [[1, S]], v \in [[-\mu M, \mu M]] \text{ and } \}$ 655 $\tau' \in](-\Delta_{\tau}'/2), (\Delta_{\tau}'/2)[]$. We also use a discrete version 656 of the dictionary, with vanishing τ' : $\{w_{\gamma}\}_{\gamma \in \Gamma}$ with 657 $\Gamma = \{ (s, \nu, 0) \in \Omega \}.$ 658

2) Inner OMP: For simplicity, in this paragraph, we omit the superscript (i) of an estimated wavelet $w^{(i)}$, and we consider wavelets as continuous-time signals.

659

660

661

677

678

679

The inner OMP is initialized with the windowed non-662 parametric estimation $R^0 w(t) = \tilde{w}(t)$. Let $R^{k-1} w$ be the 663 residue after (k - 1) iterations of the inner OMP. At iter-664 ation k, first we look for a solution $\hat{\gamma}_k = (s_k, v_k, 0)$ 665 to $|\langle R^{k-1}w, w_{\hat{\gamma}_k}\rangle| = \max_{\gamma \in \Gamma} |\langle R^{k-1}w, w_{\gamma}\rangle|$, which gives 666 initial conditions for the iterative optimization algorithm 667 converging to a local maximum, approximate solution to 668 $|\langle R^{k-1}w, w_{\gamma_k}\rangle| = \max_{\gamma \in \Omega} |\langle R^{k-1}w, w_{\gamma}\rangle|$. Thus, we obtain 669 w_{γ_k} , the atom of the inner OMP chosen at the iteration k. In the 670 following step, we update the coefficients of the orthogonal 671 projection of \tilde{w} on the vector subspace of the first k atoms 672 obtained via the inner OMP. After K iterations, we obtain the 673 decomposition $\tilde{w}(t) = \sum_{k=1}^{K} a_k w_{s_k}(t - v_k \Delta'_{\tau} - \tau'_k) + R^K \tilde{w}(t)$, which gives the parametric estimation of the stage 5 above: 674 675 $w^{(i)} = \sum_{k=1}^{K} a_k w_{s_k} (t - v_k \Delta'_{\tau} - \tau'_k).$ 676

Section III-D presents a complete view of the deblending algorithm Matrioshka OMP.

D. Matrioshka OMP Overview

Matrioshka OMP [58] stands for two OMP algorithms embedded into one another. The algorithm is illustrated in Fig. 6, where the *outer* OMP consists of the whole algorithmic loop with the *inner* OMP embedded into it and highlighted in orange. We now describe each step individually.

After the spectral analysis of the data, the second stage of 686 the processing is to split the continuously recorded signal d(t)687 into temporal frames suitable for deblending. It is worth noting 688 that the definition of windows width using a number of traces 689 is no longer compatible with the data. Indeed, the number 690 of traces (whole or parts) does not necessarily match for 691 the different sources. To overcome this ambiguity, we chose 692 to define window width in terms of time. When a window 693 break occurs between shooting times of a source, we use the 694 knowledge of the previous shooting time to exploit all the 695

²We shall see in Section III-E that, when the factor $\beta' + \alpha'(x_n^i - x_0^i)$ changes its sign between the extreme values of x_n^i , the stages 2 and 3 can be iterated, modifying the criterion (12). For simplicity, we do not present this procedure here.

⁶⁹⁶ information available in the data. Thus, the outer OMP is ⁶⁹⁷ initialized from the input data d(t) windowed by a rectangular ⁶⁹⁸ time window strictly included in the interval [0, T_{glob}] and ⁶⁹⁹ corresponding to N seismic traces for one source. We denote by d(t) the windowed signal d(t) and take it as the first residue: $R^0 d = \tilde{d}$.

Let $R^{\ell-1}d$ be the residue after $(\ell - 1)$ iterations of ⁷⁰² the outer OMP. At the ℓ th iteration, we have seen in ⁷⁰³

Fig. 7. (a) Input unblended data for the first source and (b) same data after blending. (c) Reconstruction results after L = 5 iterations of the outer OMP: events attributed to the first source, i.e., $S_{\ell}^{(1)}$ of (14) with $\ell = L$ and (d) residue $R^{L}d$ of (4). (e) and (f) Idem after L = 59 iterations. All the signals are represented in the (t, x) trace domain of Source 1. In our method, the deblended signal associated with Source 1 after L iterations is the sum of signals appearing in the graphs (c) and (d) for L = 5 and the sum of signals in the graphs (e) and (f) for L = 59.

Sections III-B and III-C how to obtain the initial conditions (11) before normalization, which allow an iterative optimization algorithm to converge to a local maximum.
Relationships allowing a fast computation of the norm of seismic events of the form (11) under Hypothesis 7 can be found in [59, Appendix C].

⁷¹⁰ In order to separate travel-path-related parameters from the ⁷¹¹ wavelet-defining ones, so that they do not intercompensate each other, we first optimize the τ , p, q and α parameters 712 and then the $(a_k, \tau'_k)_{1 \le k \le K}$ parameters. Note that the whole 713 dictionary is never created or stored due to computational 714 costs: a new element of the dictionary is estimated at each iter-715 ation. We obtain after these optimization stages the atom g_{γ_ℓ} , 716 approximate solution of (1), with $\gamma_{\ell} = (i_{\ell}, \tau_{\ell}, p_{\ell}, q_{\ell}, \alpha_{\ell}, K_{\ell},$ 717 $(s_{p,\ell}, a_{p,\ell}, v_{p,\ell}, \tau'_{p,\ell})_{1 \le p \le K_{\ell}}$). We then update the coefficients 718 $(c_p^{(\ell)})_{1 \le p \le \ell}$ of the orthogonal projection of \tilde{d} on the linear 719

Fig. 8. (a) Results obtained on synthetic data with real seismic noise added. Residue energy decreasing in bilogarithmic scale. (b) Coefficients magnitude decreasing diagram. (c) and (d) Signal-to-noise ratio increasing with the outer OMP iterations for the two sources. The signal-to-noise ratio is computed as $S/N = 10 \log_{10}(||d_s||^2/||d_s - d_d||^2)$, where d_s denotes the initial single source data, and d_d the deblended data for the same source.

⁷²⁰ subspace spanned by the first ℓ outer OMP atoms, and the ⁷²¹ weighted sums—called explained signals in the following— ⁷²² assuming we have N_s sources:

$$S_{\ell}^{(i)}(t) = \sum_{p=1}^{\ell} \delta_{i,i_p} c_p^{(\ell)} g_{\gamma_p} \text{ (for source } i = 1, \dots, N_s) \quad (14)$$

where $\delta_{i,j}$ is the Kronecker delta function. After *L* iterations, $\tilde{d}(t) = \sum_{\ell=1}^{L} c_{\ell} g_{\gamma_{\ell}}(t) + R^{L} d(t) = \sum_{i=1}^{N_{s}} S_{L}^{(i)}(t) + R^{L} d(t)$, and the deblended signal associated with the *i*th source is equal 724 725 726 to $S_L^{(i)}(t) + R^L d(t)$. To reduce the computational complexity 727 of the method, the optimization stages must be efficiently 728 implemented. An asymptotic complexity analysis of the algo-729 rithm is given in [59]. After processing each temporal window, 730 the deblended data are merged. To increase the deblending 731 quality and avoid high-frequency residual noise, windows 732 overlap. We end the section by presenting the initial condition 733 computation when the maximum magnitude of the wavelet 734 changes sign from one end of the seismic event to the other. 735

E. Seismic Events With a Phase Rotation

To find the initial conditions of \mathcal{G}_{γ} , the approach described 737 in stages 2 and 3 of Section III-B works perfectly for 738 seismic events which have the same polarity all along the 739 processing window. However, it is common to encounter 740 a "phase rotation" corresponding to events whose maxima 741 have different signs on the left and on the right edge of 742 the processing window (see Fig. 5). In this case, (12) no 743 longer represents a good objective function to maximize 744 because the algorithm tends to favour (to follow) amplitudes 745 of the same sign. To solve this problem, we modified the 746 criterion (12) to 747

$$C(i, \tau, p, q) = \left| \sum_{n=1}^{N} R^{\ell-1} d\left(\tau + p(x_n^i - x_0^i) + q\left(\frac{x_n^i - x_0^i}{x_{\max}^i - x_{\min}^i} \right)^2 + T_n^i \right) - T_n^{44} \right|$$

$$\times \operatorname{sgn}\left[\beta' + \alpha' \left(x_n^i - x_0^i\right)\right] \right|. \tag{15}$$

Fig. 9. (a) Full gather tests for the synthetic Marmousi data with added real seismic noise, the first source. Input nonblended signal and (b) same data after blending. (c) Residue after decomposition and (d) data after deblending (explained signal with the residue added).

and iterated twice the stages 2 and 3; this proved to be effective
 in our simulations.

753 F. Stopping Criteria

⁷⁵⁴ Due to the significant complexity of seismic data with ⁷⁵⁵ respect to our dictionary, it is very difficult to define a single stopping criterion applicable everywhere. Moreover, the stopping criterion must be adapted to the downstream processing. For this reason, we propose setting multiple stopping criteria for each simulation to achieve more accurate results and, at the same time, avoid wasting machine time on unnecessary precision seeking.

Fig. 10. (a) and (b) Real seismic data example: Torpille data. Input clean signal. (c) and (d) Artificially blended signal. (e) and (f) Isolated blending noise. For each image, its zoomed-in part highlighted by a rectangle is given at its top-right corner.

⁷⁶² 1) The OMP stopping criterion proposed in [45] is the achievement of a null, or at least of a sufficiently ⁷⁶⁴ small ℓ_2 -norm of the residue $R^L d$: $||R^L d|| < N_R$. This approach is intuitive, but not easy to implement, 765 as different seismic data sets do not have the same 766 amplification, nor do they have the same level of ambient 767

Fig. 11. (a) and (b) Explained signal. (c) and (d) Unexplained residue for the two sources after approximately 1000 iterations of OMP per lateral window. (e) and (f) Deblended data (explained signal of the source with the residue added) for the two sources. For each image, its zoomed-in part highlighted by a rectangle is given at its top-right corner.

⁷⁶⁸ noise or other noises which we would not want to ⁷⁶⁹ reconstruct. In other words, the meta-parameter N_R is ⁷⁷⁰ difficult to choose as it is highly data dependent. 2) One relative value related to the residue energy is the relative residual energy $||R^L d||_2^2 / ||\tilde{d}||_2^2 < E_R$. The metaparameter E_R can easily be set to some very small value 773 790

- (of the order of computation error) in the absence of noise or can be derived from the pre-estimated signal-775 to-noise ratio in the case of noisy data. 776
- In some cases the parameters N_R and even E_R are 777 difficult to define. If, in addition, the user only requires a 778 low reconstruction precision (only wants to reconstruct 779 and separate the most energetic events), it could be 780 helpful to set L_{max} —the maximal number of iterations 781 to perform-to a low value. 782
- The reciprocal condition number is used to measure 4) 783 whether a matrix is well or badly conditioned (if this 784 number is small). The condition number of a matrix 785 affects the solutions of similar linear systems of equa-786 tions: if the values of the matrix are slightly perturbed, 787 this leads to big differences in the solution; thus, we stop 788 the decomposition when this number is too small. 789
 - **IV. RESULTS**

This section shows results obtained with the Matrioshka 791 OMP algorithm, applied to a complex synthetic data set issued 792 from the Marmousi geological model [60], with real seismic 793 noise (see Section IV-A) and to real ocean bottom node (OBN) 794 seismic data acquired in Torpille (Offshore Gabon) (see 795 Section IV-B). More results on simple synthetic data examples 796 that demonstrate the performance in "laboratory" conditions of 797 the method can be found in [59]. 798

A. Complex Synthetics—Realistic Case Study 799

We tested our method on a realistic data set, generated by 800 the Allied Geophysical Laboratories of the University of Hous-801 ton from the Marmousi geological model. Martin et al. [61] 802 performed a highly precise elastic modeling to provide as 803 many of the seismic features usually present in real seismic 804 data as possible. Namely, the data contain not only primary and 805 multiple reflections, but also diffractions, head waves, surface 806 waves, scattering effects, and other realistic particularities. The 807 acquisition geometry adopted for this simulation is that of a 808 source vessel towing an airgun source at a depth of 10 m and 809 performing a shot every 25 m. The source signature is a zero-810 phase 5-10-60-80 Hz Ormsby wavelet with frequencies up to 811 80 Hz. The Ocean Bottom Cable is situated at the water bottom 812 at a depth of 450 m. We performed an artificial blending of the 813 data by attributing different parts of the data to two different 814 sources and creating overlapping shooting time patterns for 815 each source: the first source shoots regularly, with an interval 816 equal to 5 s, and the second source shoots with irregular time 817 intervals around 7 ± 2 s. 818

The first test, illustrated in Figs. 7 and 8, contains 20 traces 819 for each source, which corresponds to a 500-m-wide lateral 820 window. Fig. 7 shows decomposition residue and explained 821 signal for the first source in the upper part of the section, where 822 the signal is quite strong since it contains direct arrival and sur-823 face waves. Fig. 7(c) and (d) shows the decomposition result 824 after only five iterations of the outer OMP: several of the most 825 energetic seismic events have already been reconstructed, and 826 the residue energy has significantly decreased. After 59 iter-827 ations of the outer OMP [see Fig. 7(e) and (f)], the useful 828

signal present in the section is almost perfectly explained. The 829 leakage of Source 1 remaining in the residue [see Fig. 7(f)] 830 is present in the deblended signal associated with Source 2, 831 but with a sufficiently low energy to be eliminated as acquisi-832 tion noise by the classical downstream processing. However, 833 because of the presence of significantly weaker signals in other 834 parts of the studied sections, we continued the decomposition 835 up to 1750 iterations of the outer OMP, getting a perfectly 836 explained useful signal. The energy of the residue decreases 837 almost linearly in logarithmic scale, as shown in Fig. 8(a). 838 Fig. 8(b) shows the magnitude of the coefficients found during 839 the decomposition. Note the rapid decrease in the beginning 840 of the curve, indicating the sparsity of the transform. Fig. 8(c)841 and (d) shows for the two sources the increasing signal-to-842 noise ratio computed as $S/N = 10 \log_{10}(||d_s||^2/||d_s - d_d||^2)$, 843 where d_s denotes the initial single source data, and d_d the 844 deblended data for the same source. 845

Fig. 9 shows a test on the same data, with the entire shot 846 lines processed using sliding windows and in the presence of 847 real seismic noise. Note that most of the noise is left in the 848 residue, moreover to avoid any signal loss, the residue can be 849 added back to the explained coherent events, if there is any 850 signal left in it. 851

B. Real Seismic Data Example

In this section, we present test results on real data extracted 853 from a 3-D OBN seismic survey acquired in Torpille. The 854 acquisition used a conventional single source mode, with an 855 airgun seismic source towed at a 7-m depth with a shot-point 856 interval of 50 m. The water depth in this area varies from 857 25 to 35 m, which implies the presence of Scholte waves 858 making the data almost as difficult to process as onshore. The 859 sampling period was of 3 ms, and the listening time for each 860 shot was of 5.4 s. We blended them artificially as for the 861 Marmousi data. The clean and blended input data are shown 862 in Fig. 10(a)–(d). Note that the shooting line of the first source 863 is significantly closer to the receiver, since the useful signal 864 in Fig. 10(b) and (d) is located deeper (i.e., later in time) than 865 that in Fig. 10(a) and (c). Obviously, the further away the 866 source is from the receiver, the weaker its recorded signal is. 867 Therefore, the blending appears more aggressive for the sec-868 ond source than for the first one, as shown in Fig. 10(e) and (f). 869 The first source, however, is also significantly contaminated, 870 especially in the part where useful signals, as the primary 871 reflections, are present (below 2 s). The decomposition allows 872 us to reconstruct the most energetic physical events, such as 873 the direct arrivals, the surface waves and the guided waves. 874 A significant part of the reflections is also reconstructed, which 875 is well seen in the zoomed-in parts of Fig. 11(a) and (b). 876 However, part of the coherent signals stays in the residue 877 [see Fig. 11(c) and (d)]. Nevertheless, in order to avoid leak-878 age, the residue can be added back to the reconstructed events 879 for each source, as shown in Fig. 11(e) and (f). Note that the 880 decomposition and deblending results for the real seismic data 881 have inferior quality compared to the synthetic data with real 882 noise added. This can be explained as follows. First, the Tor-883 pille data contain a significant part of incoherent noise-which 884

our algorithm is not trying to capture—and when we blend 885 data, we sum up the ambient noise recorded at different times, 886 leading to a less favorable situation than a true simultaneous 887 sources acquisition. Second, the big difference in the energy 888 of the two sources is also difficult to handle, as sometimes the 889 energetic noise tends to be reconstructed as coherent signal. 890 Nevertheless, we were able to achieve a significant improve-891 ment of the signal-to-noise ratio for the deblending results 892 shown in Fig. 11(e) and (f): around 10-15 dB for both sources. 893 Taking into account that the deblending takes place in the very 894 beginning of the processing sequence, the residual blending 895 noise is likely to be handled by further conventional denoising 896 or other processing. Limitations of our method include poten-897 tial high computational complexity when big data sets need to 898 be processed with a high level of precision. We addressed this 899 issue by implementing analytical derivation in the optimization 900 routines and fast norm calculation, but further code optimiza-901 tions may be needed to industrialize the algorithm. Our method 902 provides both deblended signals and a sparse representation 903 of seismic data with a given precision, which is beneficial for 904 diverse seismic data processing problems. 905

906

V. CONCLUSION

In this article, we have proposed a new source-separation 907 method applied to seismic data acquired in simultaneous-908 source mode. This method consists of two nested OMPs and is 909 called Matrioshka OMP. We have proposed two mathematical 910 models of sensor signals in simultaneous-source seismic sur-911 veys. These models are justified by nonrestrictive assumptions 912 on the seismic survey and the simultaneous sources, which 913 we have stated as hypotheses. Our data-driven seismic event 914 model is based on features which are characterized by spatial 915 coherence of wavelet signals. Precisely, a seismic event is a 916 straight or slightly curved feature in the trace representation 917 of the data with a specific wavelet sufficiently stable within 918 a local spatial window, whose magnitude can linearly vary 919 according to the offset. We have deduced from this model 920 specific dictionaries adapted to raw seismic data without 921 preprocessing, and we have implemented two nested OMPs 922 with these dictionaries. For this, we have efficiently solved a 923 nonconvex optimization problem thanks to the gradual con-924 struction of the initial conditions close to the globally optimal 925 solution. Finally, we have tested our method on complex 926 synthetic seismic data with real noise and on real data. The 927 synthetic data examples presented show excellent deblending 928 results: the algorithm is capable of explaining almost all of 929 the coherent seismic events present in the data. The real data 930 example was more difficult to process, but the final results are 931 acceptable in terms of further processing. 932

In 2013, she joined TOTAL, Pau, France, to work 1124 as a Research Geophysicist in seismic acquisition 1125 and processing. She moved to Paris in 2018 to 1126 join the Total's Petroleum Basins Evaluation 1127 Department, where she is currently working as a 1128

Synthesis Geoscientist. Her research interests include seismic acquisition and 1129 processing, seismic attributes, and seismic characterization of source rocks. 1130

Michel Barret received the Engineering degree 1131 from Ecole Supélec, Paris, France, the Ph.D. and 1132 Habilitation degrees in signal processing from the 1133 University of Paris-Sud, Orsay, France, in 1993 and 1134 2010, respectively. 1135

In 1986, he joined the Automatics and Signal 1136 Processing Department, Ecole Supélec, where he 1137 became an Associate Professor in 1997 and a Pro-1138 fessor in 2011. He is currently a Professor with 1139 CentraleSupélec, Metz, France, where he teaches 1140 statistical signal processing. He is also with the UMI 1141

2958 Georgia Tech-CNRS, Metz. His research interests include stability of 1142 multidimensional digital recursive filters, adapted filter banks, multicomponent 1143 image compression, statistical processes, and signal representations. 1144

1102 1105 1106

Matthieu Bloch received the Engineering degree from Supélec, Gif-sur-Yvette, France, in 2003, the M.S. degree in electrical engineering from the Georgia Institute of Technology, Atlanta, GA, USA, in 2003, the Ph.D. degree in engineering science from the Université de Franche-Comté, Besançon, France, in 2006, and the Ph.D. degree in electrical engineering from the Georgia Institute of Technology (Georgia Tech.) in 2008.

From 2008 to 2009, he was a Post-Doctoral Research Associate with the University of Notre

Dame, South Bend, IN, USA. Since July 2009, he has been with the Faculty 1156 of the School of Electrical and Computer Engineering. From 2009 to 2013, 1157 he was based at Georgia Tech Lorraine, Metz, France. He is currently an 1158 1159 Associate Professor with the School of Electrical and Computer Engineering, Georgia Tech. He is the coauthor of the textbook Physical-Layer Security: 1160 From Information Theory to Security Engineering (Cambridge University 1161 1162 Press). His research interests are in the areas of information theory, errorcontrol coding, wireless communications, and cryptography. 1163

1164 Dr. Bloch was a co-recipient of the IEEE Communications Society and the IEEE Information Theory Society 2011 Joint Paper Award. He has served 1165 on the organizing committee of several international conferences. He was 1166 1167 the Chair of the Online Committee of the IEEE Information Theory Society from 2011 to 2014, an Associate Editor of the IEEE TRANSACTIONS ON 1168 1169 INFORMATION from 2016 to 2019, and he has been on the Board of Governors of the IEEE Information Theory Society. He has been an Associate Editor of 1170 the IEEE TRANSACTIONS ON INFORMATION FORENSICS AND SECURITY 1171 1172 since 2016.

Jean-Luc Boelle received the Engineering degree 1173 from École Centrale des Arts et Manufactures, Paris, 1174 France, in 1977, and the Ph.D. degree from the Soils 1175 and Structures Laboratory, École Centrale Paris, 1177 Paris, in 1983.

He joined the French Research Institute for Ocean 1178 Science, Brest, France, in 1983 and TOTAL, Pau, 1179 France, Oil and Gas company, in 1988. He worked 1180 and headed several research projects dealing with 1181 seismic wave propagation modeling, and seismic 1182 data acquisition and processing. 1183

Jean-Luc Collette received the Engineering degree 1184 from Ecole Supélec, Paris, France, in 1985. 1185 In 1986, he joined the Automatics and Sig-1186 nal Processing Department, Ecole Supélec. He is 1187 currently a Professor with CentraleSupélec, Metz, 1188 France, where he teaches automatic control and 1189 image processing. His research interests include 1190 hybrid filter banks and biomedical imaging. 1191
